Case II.—F. B., age thirteen years, schoolboy. As a small infant suffered from colic until weaned. For the last five years he was subject to attacks of indigestion with cramps in the lower abdomen. On November 7, 1906, after riding home from school on his bicycle and having exerted himself violently in climbing a hill in the face of a strong wind, he was taken with great distress in the lower abdomen. To relieve his agony, which was great, he was given two hot soap suds enemas, with some result. After another hour vomiting set in, which continued with little interruption for five days, or until the operation. On the second day of the attack, after repeated attempts to induce an evacuation of the bowels by enema, some blood was observed in the fluid returned. About this time blood was found in the fluid vomitus. The mother states that about this time the vomit had a very bad smell. During this time, also, the pain continued but the abdomen was not especially hard or swollen. On the fifth day of the sickness the writer was called in consultation by Drs. Warner and Bingham to see the case and found the patient lying with his face pinched and suffering, his abdomen tense but with little distention. No tumor could be palpated, but pain was distinctly greatest over the appendix. His pulse was 88 and the temperature but 100° by the rectum. Immediate operation was urged and accepted. Under chloroform narcosis a straight incision was made over the middle of the right rectus muscle; this was retracted to the left and the abdomen opened. The abdominal cavity contained a small quantity of turbid serum. Search was first made for the appendix, and as it was found enlarged and congested it was ligated with chromic catgut. In view of the history of the case, further search was made for the cause of the trouble. After removing the appendix an elongated mass was found deep down in the pelvis, which was delivered into the original wound with some difficulty, and found to be an intussusception of the ileum. It was located some distance from the ileocecal valve, but no exact measurement was taken as to its exact location. It was so covered with intestines that our failure to palpate it before operating was explained. This mass probably might have been felt from the rectum and its location showed the importance of making rectal examinations in these cases. It was fortunate for the patient that only vain attempts were made at reduction, which were made absolutely impossible by adhesions of the intussuscipiens to the intussusceptum. It was quickly decided to make a resection, and this was done by stripping the intestinal contents away from both sides of the tumor with the fingers and gently ligating the gut with broad pieces of tape about three inches from each end of the intussusception. The tumor ends of the gut were then tightly clamped with long forceps and the tumor resected. The intussusceptum was found to be gangrenous to about six inches in extent, while the intussuscipiens was still living. The adhesions had fortunately retained a large quantity of foul smelling pus which, if it had not been so tightly shut off from the abdominal cavity, would have lighted up a high grade of septic peritonitis. As these facts were not known until the abdomen was closed much soiling of the field of the operation was avoided. An end-to-end anastomosis was made with one suture of celluloiden thread at the mesenteric border, so placed as to bring the knot on the mucous surface and to bring the mesentery and the intestine together at the same time. A row of fine silk interrupted sutures piercing all coats of the bowel, with knots on the mucous surfaces, was then reinforced by a double row of Lembert sutures of fine silk, an ordinary cambric needle being used. The mesentery was sutured with No. 1 chromic catgut. All the gut in the vicinity of the operation was repeatedly swabbed with warm saline solution. The tapes were then untied and the wound closed with tier sutures, the sutured intestine being left directly under the wound. The boy was put to bed, after lavage of the stomach and a high enema of saline solution and black coffee was given. The following morning the pulse was 150 and the temperature was 105°. The slow continuous administration of hot saline solution by rectum, after

*Read before the Orange Mountain Medical Society, Orange, N. J., April 19, 1907.

the plan of Dr. John B. Murphy, was started as soon as the writer saw the then desperate condition of the patient. The beneficial effect was at once seen. The pulse improved in rate and volume, the fever slowly came down, and the dry tongue became moist, with complete loss of thirst. The effect on the urine was magical. The patient passed about three pints in the first twenty-four hours of this treatment. He thus eliminated the toxins from his blood and peritoneum. The pinched septic facial expression slowly left his face. This treatment was continued for three days. As improvement dated from the hour of the saline treatment, the writer believes it greatly determined the recovery which followed. This recovery was but little retarded by the occurrence of a fecal fistula which fortunately closed spontaneously. The boy had daily rectal passages from the day of the operation, and did not vomit once after the resection of the bowel. In one month he was walking about the house, and since has remained in excellent health.

Intussusception is the invagination, or prolapse, of one portion of the intestine into the lumen of that adjoining. It is, in other words, a telescoping of the gut. It occurs most frequently at the junction of the cecum and the ileum in about the proportion of almost three-fourths of all the cases. A little over one-fourth of all cases are therefore enteric, in distinction from the ileocecal variety. The outer tube is called the intussuscipiens or sheath, the inner, the intussusceptum. The point of junction of the two intestinal layers is called the apex. The mesentery of the gut is invaginated with it, compressing the mesenteric vessels and adding to the danger of gangrene. This brief explanation of the pathology of this affection, although familiar to all, is most important in any discussion.

The invagination may be complete or incomplete. It may be single, occurring in only one portion of the intestinal tract, or multiple, and more rarely, in two or more portions at the same time. The intussusception may be reducible or irreducible. It may be reducible and viable, or irreducible and gangrenous, or it may reduce easily and yet be gangrenous. The slough first attacks the intussusceptum as the part most liable to constriction, secondarily the intussuscipiens becomes gangrenous, if the strangulation continues. A certain amount of local peritonitis is inevitable, with more or less exudate, causing, if delay ensues, firm adhesions to form between the layers of gut, which adhesions are a great impediment to the reduction of the intussusception. Peritonitis may spread and prove a serious factor in the mortality of the cases.

The ileocecal variety is the form most frequently met with in infants, who are more liable to this disease under one year of age. In older children and adults the enteric variety is most frequent. Colic invagination is found, as a rule, in the descending colon and sigmoid. Statistics show that intussusception occurs most frequently in infancy and childhood, particularly between the fourth and twelfth month of infancy, about one-half of all intussusceptions occurring during the first decade.

Boas[1] states we are in the dark regarding the real cause of intussusception, while Eliot[2] claims that in infancy the long mesentery, giving wide excursions to the cecum, together with the frequency of colic, offers an explanation. Intestinal polypi, enteric fever, and the various pathological conditions associated with Meckel's diverticulum and the appendix he cites as existing causes. Diarrhea, intestinal cancer, ingesta, abdominal contusion, "catching cold," or what causes irregular and violent peristalsis, are other causes that have been given.

The most characteristic symptoms of this disease are, first, spasmodic pain, referred to the region of the umbilicus, and associated with this is tenesmus, like that seen with dysentery; vomiting soon appears, especially in young children, and if the obstruction is acute may later become fecal. The stools may not entirely cease, especially if the obstruction is not complete, and frequently it is not, but the character of the stools is highly important, as 80 per cent. of cases of intussusception show bloody stools. The second case cited by the writer had bloody vomitus —a rare symptom. Blood and mucus associated with tenesmus may mislead the diagnosis to one of dysentery. The hemorrhage is seldom large in amount. Later on in the case, pieces of gangrenous gut may be passed, indicative of sloughing of the intussusceptum. A distended belly is a rare symptom, as seldom is the obstruction so complete as to cause much tympanitis until very late in the disease. Should, however, tension of the abdomen be relieved by the sloughing of the intestine or the perforating of the affected intestine, temporary relief occurs as the forerunner of septic peritonitis.[3] A tumor of the noted sausage form is of great importance (if found) in making the diagnosis. Tumor is found more often in children than in adults and is found in all in about one-half of the cases. As in the case of the writer, it may be entirely obscured because of superimposed distended coils of gut. Tumor is found more often over the ascending colon and should be sought during a paroxysm of the pain. It is wise never to omit searching for it with the finger in the rectum. As the apex of the intussusception has been known to present at the anus, this should not be mistaken for a polypus or some rectal disease.

These patients rarely have much elevation of temperature unless the element of peritonitis is marked. The pulse in infancy is elevated, especially during a paroxysm of colic; but in the case before mentioned, in a boy of thirteen, it was normal, even when the gut was gangrenous five days after the onset of the disease. Shock soon ensues and is an important symptom. In infants shock may be a very early symptom. The finding of indican in the urine is said to indicate that the intussusception is located in the small intestine rather than in the large gut.

Upon the prompt diagnosis depends the cure. Death is in direct proportion to the delay. Gibson's[4] statistics are quoted by almost every writer on this subject. He studied 239 cases. Those operated upon the first or the second day gave a mortality of 40 per cent. On the third day the mortality was 62 per cent., and on the fourth and fifth days the mortality was 72 per cent., while on the sixth day it was 100 per cent. Fagge[5] cites eighteen operative cases with a mortality of 30 per cent. Clubb[6] gives the history of one hundred laparotomies, with 37 per cent. mortality. Of course, the mortality is much influenced by the age of the patient, the variety of the disease, as well as the period of time at which the operation is performed. If reduction is possible, the mortality is far less than when the case is irreducible or is gangrenous. Treves[7] states he is not aware of a single case of recovery after intestinal suture. At the Clinical Society of London, December 9, 1904, A. E. J. Barker (quoted by Moynihan[8]) stated he had never seen a recovery after resection in gangrenous cases, and never expected to see it.

One of the first successful cases of resection for gangrenous intussusception the writer can find on record is that of Dowd[9] in 1902, in a boy of four years of age. The ends of the gut were brought together in end-to-end anastomosis and the abdomen was closed without drainage. A more recent case

is that of Coffee,[10] who reports a successful case of resection for gangrenous intussusception. Although the recorded successful cases of resection are few, yet there must be many that have not been reported. The writer believes that the statistics of the mortality from intussusception for the future will be far different and better than those above quoted, because of (first) more prompt recognition of the disease and (second) of the application of modern surgical principles.

Concerning the treatment of intussusception, Ashhurst[11] states there is probably no class of cases so habitually mismanaged by otherwise intelligent practitioners. This, he tells us, is owing to the fact that these cases being rare, few physicians have the opportunity, or take the trouble, to make themselves familiar with the pathology, and therefore use irrational methods to produce a cure, and use remedies more likely to kill than to cure. He mentions as examples long and persistent efforts to reduce by injection and inflation, the use of huge doses of cathartics, even croton oil, and the giving of repeated doses of morphine. In this disease early diagnosis is the *sine qua non* of safety. The physician, having made the diagnosis, should not leave the patient until speedy means are afoot to relieve the trouble—or, in other words, he should stand by until the obstruction in the gut is relieved. Furthermore, the means are distinctly surgical. Until recent years cases of intussusception have been admitted to the medical wards of the hospitals; now this is never done.[12] Treves[13] says surgical opinion has, in the last ten years, steadily come around to advise abdominal section at the very earliest moment. Dicken[14] tells us "first, be sure you have intussusception, then operate, and nine times out of ten you will be doing the best thing for your patient and for yourself." But what can we do before we operate? Eliot says it will do no harm to try to pass a catheter into the rectum to attempt to introduce it through the intussusception, if the situation of this is low, *as a preliminary to operation*. The statement of Pepper,[15] that the first step in the treatment of intussusception should consist in the administration of opium, is, in view of modern experience, bad advice. Valuable time is lost if any protracted attempts are made to reduce by intestinal inflation, either by gas or by fluid from below. Moynihan says, "the method is uncertain, deceptive, in that reduction may be apparently complete and in reality be only partial, and by no means devoid of risk. The tendency of surgeons is very properly to abandon it or to use it only in conjunction with an abdominal operation." Eliot says, "too frequently a partial reduction only is accompanied by a disappearance of the tumor and alleviation of the symptoms, and when subsequent operation becomes necessary the conditions are much less conducive to the ultimate recovery of the patient." Maurice Richardson[16] concludes that "results have been fatally compromised by efforts at reduction." The only fatal case the writer himself has seen was made fatal by these useless efforts. The testimony of one more writer, or that of Cheyne,[17] concludes the argument. He states that in intussusception it is better to proceed at once to do a laparotomy. When the strangulated portion of the intestine is gangrenous, the condition is serious indeed—the only feasible method is to excise the involved portion of the intestine. The treatment, of course, differs as to the pathological condition. Given an open belly and an existing intussusception, its reduction by expression instead of by traction should be performed. Next, some method should be taken to prevent recurrence. This is usually accomplished by passing Lembert sutures transversely to the axis of the gut from the intestine to the mesentery near the site of the trouble. Or the intestine may be sutured to the abdominal peritoneum (Dawbarn[18]). Should reduction be impossible, a resection, rather than an enterostomy, should be performed. The making of an artificial anus in these cases has been followed by about 100 per cent. mortality. All observers hold that the ideal method is to make an end-to-end anastomosis, and if the condition of the patient is not too serious and desperate, this should be done by suture rather than by the Murphy button or other mechanical devices.

In view of the writer's experience he would like to emphasize in closing the following points:

1. The great importance of supplying *heat* to an infant under one year of age while undergoing so serious an operation as a laparotomy.

2. The infant should be kept surrounded with hot water bottles all the time while on the operating table.

3. It is well, if the case is a nursling, to let it take the warm mother's milk as soon as it has come out from the anesthetic.

4. Regular nursing is the best heart stimulant it can receive.

5. When, as in the second case reported, there is profound shock with sepsis, the plan suggested by Murphy[19] for the treatment of general septic peritonitis of giving hot saline by slow, continuous rectal irrigation, is distinctly life-saving. Its effect in washing out the toxins and thereby raising the opsonic index[20] and of increasing the amount of urine secreted, of relieving thirst and changing the dry tongue and the whole septic face of the patient, is little short of magical.

REFLECTIONS ON METHODS OF TEACHING MEDICINE.

By O. L. MULOT, M.D.,

BROOKLYN, NEW YORK.

ASSISTANT ATTENDING IN GENERAL MEDICINE AT THE UNIVERSITY AND BELLEVUE MEDICAL COLLEGE DISPENSARY.

FOR a physician who received his medical education fifteen or twenty years ago to return and take a position in a college dispensary, there again to rub elbows with students, and to watch the course of study and methods of teaching, is certainly an experience rich in food for reflection.

During that absence vast changes have been wrought; the required time of study has been more than doubled; the subjects of study have been strictly indicated for each term, and a satisfactory examination is demanded of the student at the end of the year's work before he can proceed. Thus he has been prepared to take up his practical clinical work in the third year and brings to it a certain amount of knowledge and appreciation. Under the supervision of instructors in every department of clinical work, he sees patients and personally examines them, discusses the symptomatology, differential diagnosis, and treatment of disease, with the instructors, so that when he goes out at the end of his fourth year he has personally worked over a really astonishingly large amount of clinical material. To deny that he is vastly better fitted to take up the practice of his profession than was the new graduate of twenty years ago would be the sheerest folly and could only emanate from ignorance of the present status of medical teaching.

But with all the foregoing indisputable advantages, great as they are, and the ever striving on the part of all the leading teachers to increase still more the practical work in all departments, as an onlooker I have been strongly impressed by the fact that there has been so little improvement in the method of teaching. The scheme of teaching is much the same as it was twenty years ago, only more of it. There has been no simplification; nothing to make it easier for the student to understand, and to-day the result of the teaching is still to cram the student's brain with a mass of facts of the various subjects of study, and his examination is a feat of memory and not understanding. He has simply learned his medicine, but he has not been taught to think medically.

Is this or is this not a defect? The object of all education and study is to enable the student to think independently along the lines of study, and as the medical student studies to think and practise, not alone to practise, as so many do, medicine and surgery, to this end let him learn his physiology and understand it from the physician's standpoint, and not from the standpoint of the out-and-out physiologist; in other words not physiology—physiologically but medically; not anatomy—anatomically, but medically and surgically.

True, before a student can think and reason independently, he must learn a certain number of empirical truths—facts—as a starting point; and how to think is as much a part of the teacher's duties as the imparting of the single fact or group; for only thus is the intellect, not the memory alone, developed. If the student is asked to interpret a group of symptoms, he ransacks his memory for the name of the disease of which this group stands as symptomatic, but he does not seek to explain these disturbances of equilibrium by the light of his physiological knowledge which should guide him to the seat of the pathological process. He relies upon his memory, and not on his reasoning faculties.

Certainly we have some teachers who in their lectures and clinics make clear to the student how the symptomatology points to the seat of the physiological disturbance and then proceed to argue from the pathology to the *raison d'être* of its symptomatology. Alas! these teachers are the brilliant but small minority. Such teachers are apt to forget their time limit, and from the very profundity and versatility of their knowledge become engrossed with the many aspects and phases bearing upon the subject, discussing these at the lengths merited by their respective importance and pouring forth golden wisdom from their own ripe, rich, profound knowledge, only to be cut short by the bell sounding the end of the hour. They have read a lecture extremely interesting and highly instructive to experienced physicians, who regretfully sigh that it could not be finished, but it was a lecture clearly over the heads of the students.

This lack of correlation of teaching is not confined to the schools alone, but is also evident in our text-books. I know no text-book or system to which a student or practitioner can turn to find these explanations.

There is not a branch of medical education that cannot be made interesting and its study fascinating if it is taught by one gifted with the talent for teaching. Joseph Hyrtle succeeded in making anatomy so. Why? Because he had the God-given talent for teaching. Such teachers might shock those who slavishly hold to the old orthodox methods, for in many branches there would be a tearing down of old structures. Out of the old material, however, discarding many obsolete classifications and old pedantic descriptions, many qualifying terms that tend more to obscure than elucidate, there would rise a structure simple, compact, practical, and scientifically sound, appealing to the student's understanding and powers of logical reasoning, and not entirely dependent upon his memory. When so taught, there will be less tendency among students to sneak out immediately after roll-call. The teacher is largely responsible for his students' enthusiasm.

Profundity of knowledge in itself may become a handicap, even when it goes with the teaching talent; for unless its possessor knows how to limit himself much will be unfinished and much of importance untouched. In my own time I was taught physiology by a man who did not aspire to honors in that field, still he taught it well, holding himself to that which was known; he also filled out the anatomical course, the regular professor dying during the term, and he taught us anatomy according to the physician's and surgeon's needs, in such a manner as to win the enthusiastic approbation of the class, which they took occasion to display by the presentation of a testimonial. Some years later he was called to fill the chair of his chosen work, and it was a common complaint of his students that he gave so much upon each subject that much of the course was not covered. Such men should teach only to teachers. To this end alone it will not suffice that the incumbents of chairs be all that could be desired as to knowledge and talent. It is necessary that the subordinate teachers, lecturers, and instructors, be so gifted, because much of the student's time is spent with subordinates.

If such a plan as is here only roughly hinted at, which I believe feasible, were followed, we would have in our future physicians men who might have a better understanding of medicine, productive of more originality of thought, and in their daily work not chained to a pile of text-books. Those who for years have shaped medical teaching may consider all this presumptuous; but I have spoken only of defects and needs, many of which I, and others with whom I have discussed this subject, have felt. Let them not forget that I have spoken from the position of the onlooker, who often sees more of the game than the players themselves. I know, too, that it is so easy to criticise, but I have not done so without, at least in one branch, having a clear conception of improvements that can be wrought. It is not within the scope of this article to take up such matters: the subject is vast, its possibilities grow the more one gives it thought.

CONCERNING PLAGUE.

PLAGUE, in many respects the most fearful and devastating of the diseases that occur nowadays, shows no signs of decline. In fact, in its home in the Far East, the ravages of bubonic plague are more widespread and fatal than ever before. Of course, in Asia there are certain endemic centers from which pandemics are derived, as the district of Yunnan in China, and the plague centers in Arabia and India. In China and in Asia, generally, plague has been particularly active since the year 1890. In India alone the total recorded deaths from plague during the past ten years have been considerably over 5,000,000, representing a mortality rate of one death in every sixty of the inhabitants of India. It is worthy of note that the death-rate during the later years in India has been very much greater than in the earlier, the deaths in the last five years and four months, according to official reports, having been over 4,500,000. One of the best known authorities on plague is Professor W. J. R. Simpson of King's College, London, he having gathered his knowledge from a wide experience of the Far East, as well as by careful study and investigation. Dr. Simpson delivered recently a series of lectures dealing with plague, in which he embodied the results of his stores of lore, and has thereby distinctly added to the literature of the disease.

In these lectures the disease in India is discussed somewhat exhaustively from many standpoints, and it is pointed out that, even when it is taken into consideration that India is an immense country with a vast population, the death-rate from plague is excessive, and that its continuance is a matter of the very greatest moment. Dr. Simpson states emphatically that the prevention of plague in India is the most important question for India and England at the present time, more especially for the reason that it is the sturdy peasants, the sowers and tillers of the soil, the producers, that are dying in such enormous numbers; and if these continue to die, the effect, as has been the case in all epidemics, will be a serious disorganization of the social and economic conditions of those parts of the country in which plague is epidemic, and will likewise affect gravely the state of the entire country.

However, the plague question in the Far East, viewed from a political and economic standpoint, has no direct interest for the medical profession of the United States. But the matter of its origin and spread is of the deepest concern to all civilized people, and perhaps in an intimate degree to the American people who have not yet forgotten the epidemic of plague in the old Chinese quarter of San Francisco which Mayor Schmitz tried so hard to conceal.

The modes of dissemination of plague are various. These are rats, clothes, human agency, and food. It is admitted now on all hands that, except in pneumonic cases, rats are the chief agents in the spread of the disease, although the manner in which the infection is transferred from the rat to man is still a matter for debate. As Dr. Simpson says: "There are two views, and the upholders of each have a tendency to claim that theirs is the only way. The more that is learnt of plague the more it is evident that there is no only way." Dr. Ashburton Thompson of Sydney, who has had exceptional opportunities of studying plague in that port, came to the conclusion that Simond's theory that the flea on the rat, leaving the rat dead from plague, and then biting man, transfers plague from the rat to man, explained the phenomena connected with plague. Dr. Simpson, after a careful sifting of all the evidence for and against this theory, has reached the opinion that it is doubtful whether the flea theory will account for more than a certain percentage of the fatal bubonic cases, which may vary in different circumstances in different localities.

The writer leans more to the theory that the ingestion of food contaminated with the plague virus is the cause of septicemic cases of plague. Dr. Klein has demonstrated beyond the shadow of a doubt that the plague bacilli taken in contaminated food multiply while the food is in the intestines, enter through the lymph channels or lacteals of the intestines, and invade the blood in swarms. Dr. Simpson thus thinks that, while rats are the principal agents conveying plague, food and not fleas is the more usual medium by which the disease is transferred to man.

The lecturer dealt at length with the various ways of treating plague, but that is at present, and we hope always will be, a matter of comparatively slight interest to medical men in this country.

THE BEARING OF ANAPHYLAXIS ON THE ANTITOXIN TREATMENT OF DIPHTHERIA.

WHEN we take into consideration the immense number of cases in which the antitoxin treatment of diphtheria has been employed in the past twelve or thirteen years, the number of fatalities which have been rightly or wrongly charged to its account is almost infinitesimal; it is certainly negligible as an argument against the specific treatment of first attacks of this former scourge of childhood. Recent discoveries regarding the phenomenon of serum anaphylaxis, however, contain the suggestion that there may be a real, though probably remote, danger in this therapeutic measure when resorted to in subsequent attacks of the disease.

The term anaphylaxis is used to designate the increased susceptibility to a poison exhibited by an animal which has survived a non-fatal dose of the same substance; it is thus the opposite of immunity, or increased resistance to a toxic substance following its exhibition in small doses. Attention was first drawn to this phenomenon by Richet, Rosenau

and Anderson, Theobald Smith, and Otto. The reaction is described by Gay and Southard (*Journal of Medical Research*, May, 1907) as follows: "The injection of any convenient amount of horse serum subcutaneously or intraperitoneally in normal guinea-pigs produces no ill effect. If, however, guinea-pigs are given a very small dose of horse serum, *e.g.* .0001 to .1 cubic centimeter, and ten days or two weeks are allowed to elapse, a second injection of a relatively large amount, *e.g.* five cubic centimeters, will cause violent and characteristic symptoms, followed almost invariably by death within the hour."

The possible significance of this discovery in respect of the antitoxin treatment of diphtheria was early emphasized by the fact that the phenomenon was first noted in guinea-pigs which had survived the injection of a diphtheria toxin-antitoxin mixture, and later received a large dose of simple horse serum. The fatal reaction was shown not to be due to the diphtheria toxin, but to the "anaphylactic" influence of the horse serum containing the antitoxin. In the early experiments it was noted that a very small initial dose of serum sufficed to cause an increased susceptibility after an incubation period of ten to fifteen days, but that a large dose seemed to immunize. Gay and Southard found, however, that a single large initial dose equally causes sensitivity, but only after a longer period of incubation. It was this longer period of incubation that misled the earlier observers.

The anaphylactic action of normal sera occurs, however, according to Pfeiffer, only in case the sera are hemolytic for the injected animal, hence those animals which are resistant to the toxic action of horse serum are unaffected by subsequent injections, no anaphylaxis having occurred. Whether horse serum is hemolytic for man is a question which appears not to be definitely settled. Rosenau asserts that it is; others deny this. The importance of determining the point definitely is evident, for it is toxic for man, a resort to antitoxin injections in a second attack of diphtheria might be fraught with untoward consequences. Another point which calls for exact determination, in case horse serum is hemolytic for man, is the dose necessary to produce toxic effects. It is possible that the small amount of serum in the ordinary dose of antitoxin might have no serious consequences in spite of the anaphylactic action of the former dose. But we are playing with fire here, and it is well to be sure of our ground before giving antitoxin recklessly in second attacks of diphtheria.

BLOOD INJECTIONS IN CANCER.

Professor August Bier, until recently of the University of Bonn, but now of Berlin, whose originality of thought has already enriched our therapeutic resources in numerous directions, publishes in the *Deutsche medizinische Wochenschrift*, July 18, some interesting observations in regard to the effect of injecting sterile defibrinated heterologous blood into the human being. The two varieties of blood experimented with were taken from the lamb and the pig, and it was found that the latter was more active in effect than the former. If 10 to 20 c.c. of pig's blood are injected under aseptic precautions into the human subcutaneous or other tissues, there occurs regularly at the site of injection an inflammatory process that reaches its acme in from one to three days, and then gradually subsides. This is accompanied by a slight elevation of temperature that is sometimes preceded by sensations of chilliness. Through the hemolytic properties acquired after the first injection, repetitions of the procedure are apt to be followed by an increase in the intensity of the reaction, and by graduating the doses the effect can be controlled with considerable accuracy.

Bier was originally led to conduct these observations with a view to investigating the relationship between inflammation and fever, but incidentally he tested the effect of the procedure in cases of malignant new growths. The heterologous blood appears to have no appreciable solvent effect on normal tissues, but pathological structures, notably carcinomatous masses, are profoundly modified. In ulcerative carcinomas the secretion and suppuration are nearly always checked and active destruction of the abnormal cells takes place. Two cases of inoperable carcinoma treated in this way are reported in detail. In one of these a species of strangulation of the cancer cells was caused through the violent inflammatory reaction with the formation of new connective tissue, and in the other a massive dry necrosis of the tumor mass took place. Bier does not as yet venture to predict whether the method will be found of actual use in the treatment of malignant tumors, but the results obtained are certainly striking when considered from the standpoint of the fermentative action on new growths that has been observed by Leyden and Bergel, who used liver extracts, as well as by the workers with pancreatic products. The word of caution uttered by Bier in regard to indiscriminate attempts to apply the method before its possible dangers have been more fully ascertained would seem to be well founded, however.

The Nutritive Value of Cocoa.

Cocoa is rich in food stuffs compared to other drinks in the same category, such as coffee and tea, the powdered form on the market containing from 20 per cent. to 25 per cent. proteids and from 12 per cent. to 35 per cent. fats, besides small amounts of carbohydrates, water, tannic acid, and theobromine. Its value as a food depends upon the extent to which the proteids and fats contained in it are utilized by the body. Under the direction of von Leyden, L. Pincussohn (*Zeitschrift für klinische Medizin*, Vol. 63, 1907) carried on a series of experiments on dogs and human beings to show how much of these substances was absorbed. He first established a nitrogenous equilibrium by giving a woman a mixed diet of bread, meat, vegetables, milk, and butter, about 1,650 grams in all per day, so that the total quantity of nitrogen eliminated was equal to the nitrogen ingested, the body weight remaining the same. The ordinary methods for studying the metabolism of proteids were used, the nitrogen of the urine and feces only being considered, the nitrogen in the former being a measure of the extent of the metabolism of the proteids in the body, while that in the feces was the measure of the nonabsorbed part of the nitrogen of the food. By estimating the fats in the feces he ascertained how much of them was not

utilized. On the above diet he usually found that 94 per cent. of the proteids and 99 per cent. of the fats were absorbed. When thirty-five grams of the food were supplanted by thirty-five grams of cocoa (equivalent to six cups), so that the amounts of ingested fats and proteids were the same as when the person received the mixed diet without cocoa, he found that only about 85 per cent. to 90 per cent. of the proteids were utilized, while the fats remained within physiological bounds, usually being well absorbed. The percentage of proteids utilized varied with the mode of preparation of the cocoa. As a rule, the bean is first treated with steam or some alkali, as potassium carbonate. The resulting cocoa mass, which contains 50 per cent. fat, is then put through various processes until a fine powder containing from 12 per cent. to 35 per cent. fat is obtained. Pincussohn found that the percentage of proteids utilized, while always smaller with the diet including cocoa than with the mixed diet alone, was smallest when cocoa containing a high percentage of fat was used, and when it was prepared with a high percentage of potassium carbonate, or without any, small amounts of the latter seeming to be essential. Finely powdered cocoa was better utilized than the coarse powder. The mode of preparation had little effect on the absorption of fats. Cocoa is not likely to be taken in larger quantities than six cups a day, so that it cannot form the whole, or even the greater part of the daily nourishment. Small amounts are well utilized, though not quite so well as are other foods containing practically the same percentage of proteids and fats.

The Use of the Roentgen Rays in Gastric Diagnosis.

The technique of the radiographic examination of the alimentary canal has now reached a degree of development which renders the method one of undoubted value in the diagnosis of the oftentimes obscure disorders of the digestive system. By means of the administration of semisolid foods, such as mashed potato, mingled with considerable amounts of one of the salts of bismuth, it is possible to obtain radiographic pictures conveying much supplemental or at least corroborative information regarding the conformation, position, and motility of the esophagus, stomach, and intestine, and by enclosing portions of bismuth in little bags of goldbeater's skin, which is digested in a normally acting stomach, ocular evidence of the functional activity of that organ may be obtained. Some clinicians have even succeeded in demonstrating the presence of gastric ulceration by administering bismuth in small amounts of fluid. The patient assumes various positions in order to coat the interior of the stomach as thoroughly as possible with the mixture, and some hours later the stomach is examined by means of the fluoroscope in the hope that after the exit of most of the substance into the intestine any existing ulcerating areas will still be coated with it, as it has a greater tendency to adhere to raw surfaces than to the uninjured mucous membrane. It is true that the radiographic methods are rather complicated, but their application is becoming more and more frequent in nearly all branches of medical diagnosis, and, as is pointed out by Jollasse in the *Münchener medizinische Wochenschrift*, July 16, 1907, the procedure may be regarded as almost indispensable in cases of gastric disorders in which it is inexpedient to introduce instruments into the stomach.

The Bacteriological Diagnosis of Typhoid Fever.

At the time when the intestine was considered the chief seat of the Eberth bacillus, the bacteriological diagnosis of typhoid fever was confined to the examination of the stools, and the methods used were troublesome and often unsuccessful. Castellani and Schottmüller were the first to make systematic blood cultures and to get almost constant positive results. The former removed twenty cubic centimeters of blood from a vein and added it to nine hundred cubic centimeters of bouillon, which was placed in three flasks. After twenty hours the sedimented blood looked dark, while the supernatant bouillon looked cloudy; one cubic centimeter of this culture yielded a pure typhoid growth in eight hours on Dregalsky-agar. This method proved to be the most satisfactory of those used during the past two years in von Leyden's wards, and it can easily be carried out in private practice. In the *Zeitschrift für klinische Medizin*, Vol. 63, 1907, F. Meyer publishes the results of twenty-four such bacteriological examinations, all but one of which gave positive results. In two of his patients the temperature was never any higher than 100.6° F., nor did they show any typical clinical symptoms, and in such cases, especially, the importance of an early diagnosis, from both a hygienic and a therapeutic point of view, is evident. The finding of the typhoid bacilli in the blood explains their presence in the kidneys, spleen, and other organs, and directs the therapy in a more successful direction, *i.e.* by means of serum. We may conclude from Meyer's results, and in view of the fact that patients suffering from typhoid fever frequently display but few clinical symptoms, that a blood culture should be taken in every typhoid suspect, and that a positive Widal reaction should not be waited for before a diagnosis of typhoid fever is made, especially as the former is positive early, while the latter at times does not occur until convalescence has set in. Blood examinations are therefore an important advance in the early diagnosis of typhoid fever, and by means of them a beginning epidemic may often be detected and possibly averted.

News of the Week.

Yellow Fever in Cuba.—Ten cases of yellow fever with one death are reported as having occurred among the soldiers at Cienfuegos. The patients are men belonging to the Hospital Corps, and only one case has occurred among the troops forming the garrison. It is therefore thought that the infection occurred within the hospital, which is in the same building as the Civil Hospital.

Degree of LL. D. Conferred on Dr. Carroll.—In conferring this degree upon Dr. James Carroll, Chancellor Andrews of the University of Nebraska addressed the candidate as follows: "James Carroll, doctor of medicine, major, and surgeon in the army of the United States, scholar, writer, teacher, and inspirer of youth, professor in the George Washington University, citizen of upright life, patriot, investigator, critical connoisseur of biological science, philanthropist, demonstrating for the behoof of science and humanity at the foreseen risk, the actual shortening, and the almost loss of life, the true cause of yellow fever, and for this sublime deed, standing before mankind as its most meritorious benefactor now alive, in whose presence the race should bow with bared heads. On you, in recognition of such virtues, attainments, and immortal but

unremunerable services, I do, by order of the Regents of the University of Nebraska, and in accordance with law, confer the highest academic honor granted in America, the degree of Doctor of Laws. In token whereof is given this diploma."

Illness of Dr. Markoe.—The friends of Dr. Francis H. Markoe and all his professional colleagues have been saddened by the announcement that he is critically ill. He is suffering from aneurysm of the aorta, which has compelled him to give up work and has, for the past two weeks, confined him to the bed.

Plans for New Medical Building at McGill.—Plans for a new building for the medical school of McGill University have been accepted by the Board of Governors, and it is expected that the work of construction will commence without delay. The new building will be erected on Pine avenue, opposite the Royal Victoria Hospital, and is to consist of a central block facing the campus and connected at either side with pavilions running parallel with University street and Carleton road. The cost is estimated at $500,000, not more than half of which sum is available as the result of the insurance on the old building which was burned a few months ago.

Robert Burns Hospital (Chicago).—Dr. Alex. A. Whamond and other west side physicians have purchased the property formerly occupied by the Finsen Light Institute, and have equipped the building as a general hospital, which was formally opened on July 15, with a reception. The new hospital is to be called the Robert Burns Hospital.

Memorial Hospital.—The Fernand Henrotin Memorial Hospital of Chicago is nearing completion, the faculty and directors having made an inspection of it. The formal opening will occur late in August or the first part of September.

New Jewish Hospital.—Plans have been filed for remodeling the two old-fashioned three-story and basement dwellings at 138 and 140 Second street into a hospital for the recently organized Jewish hospital, which is to be known as the Mount Moriah Hospital. It will be well equipped for both laboratory and general work. The necessary changes are to cost $10,000.

Tent Centers in Tenement Districts of Chicago.—The work of establishing tent centers in the congested districts of Chicago has been begun by the Chicago Relief and Aid Society. In these places the children may play without danger of being overcome by the heat. Each day volunteer physicians talk to the mothers on the proper care of children during the summer weather.

Advertising Medical Corporations.—The lay president of a so-called dermatological institute in this city was arrested last week at the instance of the Public Health Defense League, charged with violating a section of the laws of 1907, which provides that any person not a registered physician who shall advertise to practise medicine shall be guilty of a misdemeanor. Another part of the section under which the arrest was caused provides that no one can conduct a medical practice under the name of another, and in this case the originator of the institution under whose name it is still conducted has withdrawn from it and is in business elsewhere. It is stated that the principle involved is a very broad one, applying also to the legal profession, and that if the action is successful it will have an adverse effect on title guarantee companies, trust companies, etc., that undertake to act as attorneys.

Dirty Milk Cans.—Under a provision of the pure milk law, which went into effect in July, the officials of the Bureau of Dairy Products of the State Agricultural Department have called to account fifty milk dealers and large users of milk in this city for sending to the freight depot of the New York Central Railroad on a single night of last week more than fifty loads of dirty milk cans. The dairymen have long complained of the condition in which their cans were returned to them, and the new law requires the users to clean the cans before sending them back. A penalty and seizure of the can may be enforced by the Department.

Food Preservatives.—State Commissioner of Health Porter announces that the analysis of food products to determine whether preservatives are used, which has been conducted by the department for two months past, has shown that conditions are improving. The department made chemical examinations of canned meats and bottled beer, and fourteen samples of various kinds of canned meats examined in June were found to contain boron preservatives. In July samples of as many of these same fourteen brands as the department could find on sale were again submitted to chemical tests, and of nine that were purchased but one showed the presence of a boron preservative. Out of twenty-five samples of bottled beer two contained salicylic acid, several contained fluoric acid, and three or four showed the presence of sulphites.

Motoring and the Tuberculoopsonic Index.—According to the *Medical Press,* the tuberculoopsonic index of the gentleman who recently established a marvelous record in a twenty-four-hour endurance run in a motor car was found to have increased from 0.85 before the feat to 1.17 directly after its termination. It is suggested that an automobile is a more agreeable, if more expensive, prescription for a consumptive than codliver oil.

Opium Dens in Canton Closed.—In accordance with the recently issued imperial decree, all the opium dens in Canton were closed by the authorities on August 9. The closure was effected without disturbance, and is said to have caused general rejoicing, the streets being decorated and traversed by approving processions.

Alcohol and Prescriptions.—Forty of the druggists of Topeka, Kansas, have been examined by the County Attorney, and several of the number have admitted that their chief revenue was derived from the sale of liquors. One druggist said that in the month of July 94 per cent. of his receipts came from his traffic in liquors, amounting to more than $1,400. His prescription business for the month amounted to $4.50.

Gift to King Edward's Hospital Fund.—Andrew Carnegie has given $500,000 to King Edward's Hospital Fund. The money has been given unconditionally, but with the suggestion that reforms be instituted in the management of the fund, which it is often alleged is not administered in very economical fashion. Mr. Carnegie's gift is the second largest individual donation ever made to the fund since it was founded in 1897, the largest having been that of Sam Lewis, the money lender, who bequeathed $1,250,000 to the fund.

Cholera Feared in Russia.—The cholera situation is not improving in Russia, and it is officially announced that the provinces of Astrakhan, Saratoff, Simbirsk, Ufa, Kazan, and Nizhni-Novgorod are threatened with an outbreak of the disease.

American Public Health Association.—The thirty-fifth annual meeting of this organization will be held in Atlantic City, N. J., September 30 to October 4, 1907. The following topics have been

selected by the program committee for discussion: Milk; laboratory findings in diphtheria; immigration in its relation to public health; what nuisances should be abated by the Board of Health; control of the so-called minor infectious diseases; vital statistics and the value thereof; the construction and care of streets from a health standpoint. The president of the association is Dr. Domingo Orvananos, Mexico City, Mexico, and the secretary is Dr. Charles O. Probst, Columbus, O.

Seventh Annual Conference of State Sanitary Officers.—The next conference of the Sanitary Officers of this State will be held in Convention Hall, Buffalo, October 16, 17, and 18. In connection with the conference, and during the whole of that week, there will be held the first demonstration of the department's traveling tuberculosis exhibition. Every municipality and every institution or society which is carrying on antituberculosis work in any part of the State is invited to contribute photographs, charts, and tables showing the operations, results, statistics, and methods of work to this exhibition in order that the State Department of Health's exhibition may be complete. In addition there will be shown a series of models of slow and rapid sand filters and of a septic tank and contact beds. There will also be on exhibition a series of charts and tables showing the incidence of typhoid fever in the different municipalities in the State; maps showing the water sheds of the State, and similar illustrative material. The State Hygienic Laboratory will have its traveling laboratory outfit and other outfits, apparatus, etc., on view.

Medical Society of the Missouri Valley.—The twentieth annual meeting of this association will be held in the city of Council Bluffs, on September 5 and 6, under the presidency of Dr. O. Beverly Campbell of St. Joseph. Invitations to be present have been extended to the presidents of the various State associations within the province of this society, as well as to other distinguished men in the profession. The secretary of the society is Dr. Chas. Wood Fasset of St. Joseph, and Dr. Donald Macrae of Council Bluffs is chairman of the committee of arrangements.

Obituary Notes.—Dr. Wm. Thomson, emeritus professor of ophthalmology in Jefferson Medical College, died at Philadelphia on August 3, at the age of seventy-four years. He was graduated from Jefferson Medical College in the class of 1855, and on the breaking out of the Civil War he was made a surgeon in the United States Army, being on active duty with the Army of the Potomac before the battle of Bull Run. Subsequently he had charge of general hospitals at Alexandria, Va., and Portsmouth. In 1863 he was made surgeon of the Charles Douglas Hospital at Washington and, in 1864, Medical Inspector of the Department with 23,610 beds under his direct supervision. In conjunction with the late Dr. William F. Norris, he made a study of photography in its applications to surgery, and as a result of this work a photographic bureau was established by the Surgeon-General of the Army. On his return to civil life, Dr. Thomson took up the work of ophthalmic surgery as a specialty, and made a study of color blindness among the employees of the Pennsylvania Railroad, by means of which he was able to show that many accidents were attributable to this defect. He was many years ago made clinical professor of ophthalmology in Jefferson Medical College, and was subsequently elected professor of ophthalmology, and finally emeritus professor. Since 1868 he has been more or less actively connected with Wills Eye Hospital.

Dr. Leonard S. Taylor of Elgin, Ill., died on August 6, at the age of forty years. Some weeks previously he had infected himself by a needle prick at an operation in a septic case, and he succumbed to the resulting septicemia.

Dr. George H. Stanley of Pawtucket, R. I., died on July 30, at the age of sixty-one years. He was born in Dixfield, Me., and received his medical degree from Harvard in the class of 1870. He had practised in Pawtucket for about thirty-five years, and for a time held the office of City Physician.

Dr. Sophia Hall of Council Bluffs, Neb., died on July 27 of old age, in her eighty-fifth year. She was born at Watertown, N. Y., and was graduated from the medical department of the University of Michigan after reaching the age of fifty years. She was once resident physician of the South Framington, Mass., Reformatory prison, and for four years was superintendent of the Council Bluffs W. C. A. Hospital. She retired from practice about fifteen years ago.

Dr. James F. Canavan, assistant physician on the staff of the Northern Michigan Asylum, died at Traverse City, Mich., on July 27, at the age of thirty-one years. He was graduated from the University of Michigan eight years ago.

Dr. George W. Gilfillan of Mount Pleasant, Ia., died on August 3, at the age of seventy-two years, after a long illness. He had practised for many years at Milton, Ia., and had been a resident of Mt. Pleasant for about three years.

Dr. J. S. Deziel of Barre, Vt., died suddenly on July 31, at the age of forty-one years. He was born in Montreal and was graduated from Laval University in that city in 1893. A year later he began practice in Barre.

Dr. Thomas B. Brown of Gallatin, Tenn., died on July 30, at the age of thirty-two years, after an illness of two weeks. He was a native of Gallatin, and received his medical education at Vanderbilt University. He had practised in Gallatin since the time of his graduation a few years ago.

Dr. Lucien Banks died at Mifflintown, Pa., on August 3, at the age of sixty-six years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1867. He was for a time a member of the State Legislature.

Dr. Orlando S. Reynolds of Cumberland, Md., died on July 26 of typhoid fever at the home of his father, Judge Francis M. Reynolds, at Keyser, W. Va., at the age of twenty-eight years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1902. He served a term as interne in the Episcopal Hospital of Philadelphia.

Suicide of Animals.—It has often been alleged that animals at times commit suicide, and their suspicious behavior when captured is cited as evidence of this statement. Experiments have proved the fallacy of this view, however, notably those carried out some years ago by Dr. E. Ray Lankester, director of the Natural History Department of the British Museum, and Professor Bourne of Madras. Scorpions were confined in an extremely hot place, from which escape was impossible, and their frantic gymnastics were carefully studied. As in the case of the tortured rattlesnake biting its own body, the action of the scorpion in an apparent attempt to put an end to its sufferings by stinging its head was purely muscular, and Dr. Lankester himself compared the action to the biting the dust attributed to men who die in hand-to-hand struggles, or to the biting of their own hand or arm by children in a paroxysm of anger.

Correspondence.

PRIMARY TYPHLITIS (CECITIS) WITHOUT PERITYPHLITIS (APPENDICITIS).

To the Editor of the Medical Record:

Sir:—In the July 27, 1907, issue of the Medical Record one might gather from Dr. Beverley Robinson's letter that he was a prior authority in advocating the view that primary typhlitis (cecitis) could exist without perityphlitis (appendicitis). If the writer of that letter will turn to my article, "Observations on the Peritoneum in Twenty-five Autopsies," in the *American Journal of Obstetrics* for February, 1895, he will observe the same views published by me twelve years ago. In that article he may read the following sentences: "All the peritoneal adhesions in the cecoappendicular region are not due to the appendix." "Similar adhesions are as frequently found under the sigmoid flexures." "The chief peritoneal adhesions occur on both sides of the psoas and iliac muscles." "These peritoneal adhesions are due to the irritation produced by the contraction and relaxation of the psoas and iliac muscles." "The cecum is frequently surrounded with adhesions, while the appendix is absolutely free." "In the 80 per cent. of adhesions found about the cecoappendicular region, about 55 per cent. were cecal and 25 per cent. appendicular." In 1894 I demonstrated that the peritoneal adhesions found in the right—ileocecoappendicular region (7 per cent.), and in the left—mesosigmoid and sigmoid (80 per cent.) were due to trauma of the psoas muscles. In April, 1901, in the *Annals of Surgery*, I published an article on perivisceral peritoneal adhesions in the right and left iliac fossæ, detailing findings in 300 male and 118 female autopsies. Several hundred further autopsies have confirmed my views that typhlitis and perityphlitis can coexist or exist independently of each other. Hence, twelve years ago, I suggested ample evidence of typhlitis to distract attention from the "overburdened attention to the appendix." For almost a decade these views—that trauma by the psoas muscles produces perivisceral peritoneal adhesions in the bilateral iliac fossæ—remained practically dormant, *i.e.* safe in the medical archives and safe from the eyes of physicians. From more specialized study in the right iliac region, observers were compelled to recognize the above facts in regard to typhlitic peritoneal adhesions, entirely separate and independent from the periappendicular peritoneal adhesions. It is evident that pericecal adhesions (peritoneal or cellular) and periappendicular adhesions (peritoneal or cellular) originate from within the intestinal canal, *i.e.* the etiology of the perintestinal (pericolic or periiliac) adhesions is the transmission of pathogenic germs from the endointestine. In other words, the trauma of the psoas muscle during colitis produces perityphlitis (pericecitis), perityphlitis (periappendicitis), and perisigmoiditis. Pericecal adhesions and periappendicular adhesions are common observations in autopsy, and may coexist or exist absolutely separate, or either may exist without the other. I can assert this from personal autopsical abdominal inspection in some seven hundred subjects in the past fifteen years. I have observed symptoms of perityphlitis of pronounced type subsequent to appendectomy, which were evidently from endocolitis, resulting from typhlitis or resulting in typhlitis (cecitis). I believe scores of appendices are removed merely for typhlitis. It is high time that the "pathological clearing-house" should inform the on-making-a-diagnosis-of-appendicitis-operate physician that there is more typhlitis than perityphlitis. The appendix cannot and must not be made the scapegoat for every "bellyache." When the surgeon boasts of removing a dozen appendices in a single day is this similar to animal castration—prophylaxis? Every physician who respects medical science must learn by slow degrees that pericolitis (cecitis, colitis hepatica flexura, colitis lienalis flexura, colitis flexura sigmoidea, colitis rectalis) is a prevalent disease, existing perhaps in at least 90 per cent of adults. Pericolitis arises from endocolitis, exactly as perityphlitis from endotyphlitis, exactly as perisalpingitis arises from endosalpingitis. The appendix is suffering from surgical brain storms, from scalpel storms, from commercial storms, and time, with honest surgery, will demonstrate that the appendix presents but a fraction of colonic disease which may induce similar symptoms to that of perityphlitis (appendicitis).

Byron Robinson, M.D.

Chicago

Dr. F. S. Fielder of 1 West Eighty-first street, New York, writes that the position of assistant physician in a dispensary for treatment of diseases of children is vacant, and candidates for the place are requested to communicate with him.

OUR LONDON LETTER.

(From Our Special Correspondent)

ST. BARTHOLOMEW'S NEW BUILDINGS—LIVERPOOL TROPICAL SCHOOL—NEWS OF THE FOURTH EXPEDITION OF THE LONDON TROPICAL SCHOOL—THERAPEUTICAL SOCIETY—MAITLAND SANATORIUM—PURE MILK AT LEEDS—OBITUARY.

London, July 20, 1907.

The Prince of Wales, who was accompanied by the Princess, went into the city on Tuesday afternoon and opened the new casualty and out-patients' department of St. Bartholomew's Hospital. The new buildings occupy an area of 42,000 superficial feet, with a frontage on Gilliopur street of 163 feet. It is hoped the new block is not only sufficient for present needs, but capable of adaptation for the future requirements of medical science. Its cost has reached £130,000. It is six stories in height. On the ground floor the waiting hall is 140 by 48 feet and calculated to accommodate 850 patients. Around this hall are twenty-one consulting rooms and two small operating rooms. The ventilation here is on the plenum system and the air, it is reckoned, will be changed ten times an hour. Above are separate medical, surgical and eight special departments, each complete and self-contained. At the top is a lecture theatre opening onto the roof. Lifts, eleven in number, provide for access of patients, etc., to all parts. A good deal of fire-resisting material has been employed in the building and it is lighted by electricity.

The Prince, who is president of the hospital, was presented with an address recalling the fact that, founded in the reign of Henry I., the hospital received important privileges from Edward II., the first sovereign who had been called Prince of Wales, and that out-patients' service began under William III. The Prince, in reply, said he was glad to come with the Princess and to note how, from the earliest days, British sovereigns and their families had been associated with St. Bartholomew's, and he was proud to think that the presidency so long held by his father was, on his accession, continued to himself. He then declared the building opened in the usual way and the Princess, having assented to be made a governor, the "charge" was read over to her in the ancient form and a "governor's staff" handed to her. Their Royal Highnesses were then conducted over the buildings.

Liverpool is still keeping her Tropical School to the fore. On the 15th inst. the president, Sir Alfred Jones, presided at a farewell dinner to Dr. Barrett, Dr. Yorke, and Dr. J. L. Todd. The two former are going out to Africa, the last is returning to Canada. Sir R. Boyce said Dr. Todd was the finest specimen of an imperial student. He came from Canada and devoted his time and talents to tropical medicine. He also contributed some £200 a year to advance research on the subject, chiefly towards the foundation of the Runcorn Institution, in which the finest scientific work had been done and which he hoped would be permanently united to the Liverpool school. Dr. Todd, in his reply, mentioned that due honor had not yet been done to Dr. Dutton, who gave his life for the work and in memory of whom a professorship had been proposed, but only one-fourth of the necessary fund had been subscribed.

The American Consul proposed "the study of tropical medicine," a toast which was honored with enthusiasm.

To-day comes gratifying news from the fourth expedition of the Liverpool school sent to Africa to study trypanosomiasis last May. It is in the shape of a telegram to Sir A. Jones, announcing satisfactory progress. This expedition reached Kalomo on June 10 and was received by the Administrator, who gave the members every facility for their work and entertained them hospitably. It is intended that one of them, Dr. Kinghorn, shall proceed to Fort Jameson, starting at the close of this month. The other, Mr. Montgomery, will go westwards to the river Kafue, up that stream towards the Congo, and then strike across country to meet Dr. Kinghorn on the river Luapala about November, traversing all the time the territory infested by the tsetse fly. The object is to study sleeping sickness on the spot, the prevention of its spread to districts not yet infested by the fly, the distribution of biting insects and animal diseases caused thereby.

As an addendum to the foregoing I may mention what took place this day week at the London Tropical School. The portrait of the Hon. Bomanji Petit of Bombay was unveiled before a distinguished audience of Parsees, the staff of the school and others. Mr. Petit was the donor a few years ago of £7,000, and Sir P. Manson, in a speech, said but for this the school would have been greatly cramped. He also regretted that London citizens had been so backward to support the work and contrasted their lack of patriotism with the liberality of Liverpool towards its tropical school. Mr. D. Petit, the son of the donor, said his father's greatest reason for the gift was

that one of the objects of the school was the betterment of the suffering multitudes of India, and such a result would be his greatest reward.

The Therapeutical Society celebrated its transformation into a section of the Royal Society of Medicine in a manner as serious as that which has characterized its career. Nothing less than a trip to Oxford was arranged. Sir Thiselton Dyer received the members who made the excursion at Queen's College and conducted them to the Museum, where Prof. Osler showed the library and took them on to the laboratories. Prof. Gotch explained his recent researches on the heart and a method of immediately determining the point of near vision in anyone by the different focal lengths of the red and violet rays. Prof. Ramsden showed experiments on the separation of solids in solutions and suspensions. Prof. Thomson and Dr. Gibson exhibited anatomical and pathological things of interest. Lunch in Queen's College, a garden party at Dr. Osler's, and, of course, a dinner in the evening, completed a very full day's program greatly enjoyed by many.

The Maitland College Sanatorium for consumptive workers was started in 1899 and affords accommodation for twenty-five patients.

At Leeds a voluntary society established a year ago a depot for supplying pure milk, as the Corporation had no power to do so. But the Health Officer has made a report on the working. He concludes that, making allowance for the mortality of the first week of life and for those born moribund, there has been a saving of life of 25 per cent. among the children using the society's milk, as compared with those living in the same district at the same ages and during the same seasons, fed otherwise. The experiment was on a small scale, but as far as it went was more successful than he could have anticipated.

It is only a year ago that belated honors were awarded to Sir W. H. Perkin, F.R.S., the discoverer of aniline dyes, and whose other contributions to chemical science brought him such fame throughout the world but so slight recognition at home. He died on July 14, after a brief illness. A month ago Oxford conferred on him her D.C.L.

Another eminent chemist died on the 15th of July—August Dupré, Ph.D. He was for many years lecturer on chemistry at the Westminster Hospital, was a great authority on water analysis, and had been employed by the Government in reference to explosives and other subjects.

Dr. Lloyd Owen, Consulting Surgeon to the Royal Portsmouth Hospital, was born in that town in 1845 and died on July 4th last. He was a graduate in arts and medicine of Trinity College, Dublin, B.A., M.B., and M.R.C.S., all in 1866. He was for a time settled at York, but in 1870 returned to his native town and some years later was elected on the hospital staff, on which he served for about thirty-five years. He was greatly esteemed by his brethren.

Dr. J. S. Stocker, who died on the 18th, was born in 1826, qualified in 1849, took M.B., London, with honors in medicine and surgery in 1851, and proceeded to M.D. in 1853. He had been on the staff of Samaritan Free Hospital and held other appointments. He was for several years Examiner to Apothecaries Society and also a member of the Court, and became in due course Warden and Master.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

MARMORECK'S SERUM—A TUBERCULOSIS REACTION—THE GERMAN SOCIETY FOR THE PREVENTION OF TUBERCULOSIS—CHANGES IN PROFESSORIAL POSITIONS—NECROLOGY.

BERLIN, June 25, 1907.

At a recent meeting of the Berlin Medical Society a very interesting paper was read by Marmoreck of Paris on the subject of recent work in tuberculosis. His investigations were founded on the discovery of bacilli of little virulence in the blood of tuberculous guinea-pigs, and the fact that these bacilli did not induce any lesions, or only very mild ones, when introduced into the bodies of healthy animals. By making use of attenuated tubercle bacilli, Marmoreck succeeded in showing that guinea-pigs exhibit a hereditary disposition to the disease in cases in which the mother suffered from advanced tuberculosis at the time of birth. In predisposed animals it was chiefly the lungs that were affected. In pulmonary tuberculosis the degree of infection depends on the virulence of the bacilli and the powers of resistance of the body. This was shown by experiments in which the bacilli had been reduced in virulence by quinine, or had been reactivated again by injections of tuberculin. Marmoreck demonstrated an antituberculosis serum which enabled him to prevent the development of the disease in experiment animals. Its action is most effective when it is injected intravenously. It is difficult to estimate the effectiveness of the serum for human use, because of the increased susceptibility to serum albumin that usually develops during the third week of use. To obviate this the serum may be given per rectum, or three weeks of rest may intervene between three-week courses of injections of ten treatments each. Good results have been obtained by means of the serum in cases of surgical tuberculosis, but in pulmonary tuberculosis it has not been so satisfactory, owing to the fact that mixed infections are often present.

Another guest who spoke at the same session was Pirquet of Vienna, who described an early reaction in tuberculosis. He began by calling attention to the fact that at the second smallpox vaccination a local reaction appears within twenty-four hours, which is not observed at first vaccinations. The same thing is true of tuberculin injections. On inoculating tuberculous children with tuberculin it was found that red papules appeared at the site of inoculation. Observations on 500 children showed that the reaction had diagnostic value only when the children were not more than a year old. It is not seen in children suffering from tuberculous meningitis, or miliary tuberculosis. The fact that older children and grown persons usually give the reaction is evidence that in these cases tuberculosis has been, or is, present.

In the course of the animated discussion that followed, Neumann reported no results in eighteen cases of surgical tuberculosis treated with Marmoreck's serum; Sonnenburg said he had had some good results, and Landau spoke of improvement in two cases of genital tuberculosis in women. Hoffa had seen improvement follow the rectal administration of the serum in bone and joint tuberculosis, in conjunction with surgical treatment. A. Meyer reported unfavorable results in cases of laryngeal tuberculosis. Stadelmann reported five tuberculosis cases of moderate severity in which he was inclined to think that there had been but little effect, and that some complications appeared to be referable to the serum.

The recent ninth session of the German Society for the Prevention of Tuberculosis was more successful than those of previous years. The physicians of Berlin especially have criticised severely the sanatorium movement, for which many millions are expended every year in Germany, alleging that the results are not commensurate to the outlay. While it must be admitted that the permanent results achieved by the sanatoria are not particularly brilliant, in the discussion attention was called to the many other advantages attending treatment of this sort, such as lengthening life, preservation of the earning capacity for some time, and the education in hygiene. These were considered sufficiently noteworthy to justify the existence of the institutions. The public sanatoria have been particularly useful in affording the starting point for the establishment of convalescent homes and similar institutions of various sorts. Among the communications presented the following may be mentioned: Schröder spoke of the permanency of sanatorium cures. When it becomes customary to treat tuberculosis suspects in ordinary sanatoria and convalescent homes, there will be room in the tuberculosis sanatoria for patients with signs of an active process. Three months of treatment usually suffice for patients without fever. Tjaden of Bremen advised a more extensive resort to the advantages offered by the North Sea climate for the prevention of tuberculosis. Under the care of the physicians connected with sanatoria, pulmonary patients could enjoy family life at the sea, since numerous houses could be obtained at a low rental, especially in winter. Bandelier's paper on the tuberculin treatment gave rise to an active discussion. It appeared from this that this method of treatment is now more popular among institutional physicians than formerly, and good results have also been obtained by its means in dispensary practice. Observations were reported on Marmoreck's serum, Maragliano's serum, and Spengler's perlsucht serum, but the most used and apparently most satisfactory preparation was Koch's alt-tuberculin. This may be given at first in doses of 0.01 mg., gradually increasing the amount without causing any active reaction. In this way all injury to the patients and the danger of miliary tuberculosis and tuberculous meningitis may be avoided.

It is many years since there has been as much shifting about of professors as has taken place of late. Bier of Bonn has received Bergmann's chair; his own position has been filled by Garré of Breslau, who is succeeded by Küttner of Marburg. In gynecology several chairs are to be filled—that of Winkel in Munich, of Werth in Kiel, of Martin in Greifswald, of Ahlfeld in Marburg, and of Rosthorn in Heidelberg, who will probably succeed Chroback in Vienna. Among those who have recently died are the well-known Berlin clinicians, Ottomar Rosenbach and Moritz Litten, and Jürgensen of Tübingen. Only a few days ago the death of the well-known Berlin psychiatrist, E. Mendel, occurred.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 1, 1907.

On Neurological and Psychiatric Diagnosis.—Lewellys F. Barker says that the diagnosis of nervous and mental diseases made but slow progress until comparatively recent times. Mere clinical observation unaided could do but little until laboratory studies had supplied some preliminary knowledge of the structure and functions of the nervous tissues, and until the growth of psychology as a science had yielded some insight into the workings of the normal mind. The peculiar and complex structural organization of the nervous system was appalling to the majority of investigators, and it was but little wonder that the majority of physicians have preferred to work at problems which seemed easier to solve than those which the neurological and psychiatric inquirer was compelled to face. Romberg realized the value of applying physiological knowledge to the study of neuropathology and to neurological diagnosis, and he gave modern clinical neurology a firm foundation by developing knowledge concerning disease of the peripheral nerves. In psychiatry a great step forward was taken when Griesinger made it clear that the science was a part of neuropathology and inseparable from it. His recognition of the defects in medical teaching of neural and mental phenomena led to the foundation of special clinics. Modern neurological diagnosis was a direct outgrowth of the physiological research undertaken on the nervous system about the middle of the last century. The laboratories of anatomy, physiology, and pathology have afforded the data for the diagnosis of the seat of lesions and their nature. Perhaps the greatest progress making at present lay in the improvement of methods of investigating the psychic states and processes in nervous and mental diseases. Among the more interesting features of contemporary psychiatric diagnosis was the attention which is being paid to the so-called psychoanalytic method. A great impetus would be given to neurological and psychiatric diagnosis in America if psychiatric clinics were to be established in connection with every great hospital or medical school. This country is fifty years behind Germany, Italy, and France in the recognition of this need, but there can be no doubt but that America will sooner or later lead in this, as she is doing in other sciences.

New York Medical Journal, August 3, 1907.

A Case of Carcinomatous Metastases in Unusual Sites.—The chief point of interest in this case, reported by George L. Peabody relates to the unusual sites at which metastatic deposits were found. The organ primarily affected was the right breast. There were metastases in situations where they are common enough, such as the lung, kidneys, thyroid, and suprarenals; but it is uncommon to find microscopic deposits of carcinoma in the pia of the brain and cord and in the peripheral nerves. These deposits in the meninges were at the autopsy all absolutely invisible to the naked eye, and for the most part were discovered only by a general microscopical search for them. Only one of those found in the peripheral nerves caused a change in the appearance which the naked eye could detect, and that was a slight bulbous enlargement of the trunk nerve of the cauda equina. A matter of secondary interest was the development of what might be called a partial Addison's disease, the skin pigmentation being probably connected with the disease of the suprarenals. This pigmentation was chiefly confined to the skin in front of the chest and was not visible in any mucous membrane.

Etiology and Treatment of Pruritus Ani.—Herman A. Brav says that it is sometimes impossible to ascertain the cause of pruritus ani, but in the large majority of the cases the following are the most common exciting causes: Constipation and fecal impaction; local disease of the rectum or anus; want of cleanliness in the anal region; pediculi and seat worms or vegetable parasites; constitutional or systemic disease; diet and irregular habits. Again pruritus might also be a reflex phenomena of uterine or bladder disturbances, excessive and perverted sexual indulgence, and lastly some disease of the brain and cord, or senility. In the treatment of pruritus ani the cause must be sought for and removed. Where no distinct cause can be found the diet must be regulated. Meat should be used sparingly and overseasoned food avoided; likewise alcoholic stimulants and tobacco, tea, and coffee. He finds a soothing application most reliable: ℞ Chloral and camphor, ʒiv; rub these into an oil and then add: Unguenti simplicis, pulv. acidi boraci, aa, ʒiv. M. S. Apply with a brush three times daily after cleansing the parts with hot water. In some cases the addition of 20 grains of carbolic acid, in others again 20 grains of menthol, is extremely beneficial, and is often sufficient to secure a good night's sleep. Where more heroic measures are required he employs successfully pure carbolic acid, the saturated solution of nitrate of silver, or the Paquelin cautery.

The Leucocytes in Dengue.—From the observations of Edward B. Vedder the following conclusions are drawn: (1) Leucopenia is a constant feature of dengue. (2) A marked reduction in the polymorphonuclear count takes place early in the disease; is very evident by the second or third day, at latest, and this reduction is constant, with slight variations, throughout the course of the disease, until convalescence is complete, and possible for some time after convalescence. (3) Coincident with this decrease in polymorphonuclears is an increase in the small lymphocytes, which takes place with equal rapidity and is of a similar duration. (4) There is a gradual though much more moderate increase in the large lymphocytes. (5) There is a similar gradual, but slight, increase in the eosinophiles.

Examination of the Eyes of the Pupils in the Public Schools of Memphis.—J. L. Minor makes a comparison of the whites and blacks. The entire number of pupils examined was 5,030. Of these the whites contributed 3,181, 2,685 with perfect sight and 465 with imperfect vision, 89 of whom were absent when he made his examination, leaving 376 whom he did examine. The negroes contributed 1,849, 1,726 with perfect and 123 with imperfect vision, 40 of whom were absent when he made his examination, leaving 83 whom he saw. Among the whites were 42 cases of corneal opacity in each eye, with average vision of two boys and two girls, 20-70; two cases of heterochromia; one case of albinism; one of nystagmus; one of dislocated lenses; one of zonular cataract; one of optic neuritis; one of phthisis bulbi; ten of strabismus convergens; one of strabismus divergens. An accompanying table is interesting as showing practically a relative diminution of hyperopia, and increase of myopia, from the lowest to the highest grades. Among the blacks were eight cases of corneal opacity; one of retinochoroiditis, two of phthisis bulbi; none of strabismus. The accompanying table is interesting as showing not a single cases of myopia. Not only were the blacks free from myopia, but their average for perfect vision was two and a half times as great as in the whites, the proportion of badly seeing whites being 1 to 6 and black 1 to 15. There were no records of pupils with vision of 20-30.

Journal of the American Medical Association, August 10, 1907.

Gonorrhea as a Factor of Depopulation.—J. T. Johnson accepts the larger estimates of the frequency of gonorrhea in the male, calling it "the most frequent of adult diseases," and attributes to it largely the decreasing birth rate. Statistics show, he claims, that men are responsible for from between 78 and 70 per cent. of the sterility of the world, the cause being bilateral gonorrheal epididymitis, and are also responsible for a large part of the involuntary sterility of the female. The often quoted estimate of half the abdominal operations in the world being due to gonorrheal infection, falls far short, he thinks, of the actual facts. Its influence as a depopulator is shown not only in causing these mutilating and unsexing operations, but also by the production of what is known as "one child sterility," and in the recognition of its activity as a causer of abortions and premature deliveries far more often than was formerly supposed. It is also an important factor in the production of extrauterine pregnancy, and we have the authority of Jacobi and Currier that the "vulvovaginitis of little girls," which is generally of gonorrheal origin, is responsible for the frequent retardation and even prevention of the development of the female reproductive organs. The effect in adult life is to render them sufferers from amenorrhea and dysmenorrhea and practically sterile. It is a frequent and troublesome institutional disease, originating in gonorrheal infection, but spreading in other ways, of course, than by sexual connection. Johnson says that gonorrhea may be considered to have fairly earned the title of the "chief moral and physical pest of our age," and, in contradistinction to tuberculosis, might be called "the great black plague."

Clinical Method for Determining the Alkalinity of the Blood.—Herman M. Adler discusses the desirability of a practical clinical method for determining the alkalinity of blood. He notes the two general methods by which the reaction of a fluid may be quantitatively measured: (1) Titration to an end point; (2) determination of the H and OH ionization. The former yields information concerning the amount of base or acid present in a solution, but no direct evidence concerning the exactness of the equilibrium. The latter yields no direct information regarding the absolute

amounts of base and acid in solution, but gives evidence concerning the intensity of alkalinity, that is, the condition of the equilibrium. Heretofore only titration methods have been used on account of the difficulty of technic and the want of an indicator to show the slight degree of ionization in the blood serum. Salm, however, has shown that rosolic acid and neutral red give sufficiently sharp indications at the degree of ionic concentration of the blood. Adler found that rosolic acid with 1 c.c. of rabbit's blood gave a pink color which could be compared with a standard. Laked blood from which the proteids had been removed by coagulation by heat gave the same degree of color. By excluding the corpuscles he was able to avoid the difficulty due to the color of the blood and found that a drop of serum from a capillary tube produced a strongly marked red color when allowed to fall on prepared rosolic acid test paper which contrasted well with the delicate salmon pink of the unchanged parts of the paper. The red color indicates alkalinity. The serum in two cases of diabetic coma and in a case of meningitis accompanied by acetonuria did not produce this change in color, but the blood was alkalin in cases of meningitis without acetone in the urine.

Treatment of Tetanus by Intraspinal Injections of Magnesium Sulphate.—G. Canby Robinson reports a case of tetanus occurring in a boy, aged 11, with no history of traumatism or abrasion, other than a small swelling on right side of head, in whom the illness set in eleven days before his admission to the Pennsylvania Hospital. The first symptoms had been slight pain and stiffness in the jaws, diagnosed as muscular by the attending physician. On the sixth day, after playing ball, there was profuse sweating followed by stiffness of the right side, especially the leg. On the following day—the seventh—there was general rigidity, which increased until his admission to the hospital, at which time abdominal pain was the chief symptom complained of. A diagnosis of tetanus was made and a lumbar puncture was made; about 8 c.c. of cerebrospinal fluid was withdrawn and 3 c.c. of a 25 per cent. solution of magnesium sulphate were rapidly injected. Five minutes later the neck was less rigid; in an hour there was distinct relaxation of the muscles. In two and one-half hours the boy was drowsy, his neck could be freely moved and his jaws separated; the abdomen was soft, the legs and arms relaxed; no knee jerk could be obtained. Six hours after the injection the rigidity began to return and 18 hours after it was almost as bad as on admission. On the evening of the second day another injection was given; 3.5 c.c. of the solution was injected. The small swelling on the scalp—which was first described by the boy's mother on this day—was excised. The tissue contained a subacute abscess, but no tetanus bacilli could be found in either smears or sections. From this time the patient improved slowly till the twenty-third day, when the temperature reached normal not to rise again; after this the improvement was marked, and the boy was discharged on the fifty-ninth day. Besides magnesium sulphate in the treatment, sodium bromid, 1 dram, and chloral hydrate, 30 grains, in twenty-four hours, were used during the first two weeks. Bromids were given throughout the illness, and a few doses of morphine, ⅛ of a grain, were employed hypodermically. The boy weighed 65½ pounds on the forty-sixth day, but weighed 70 pounds when discharged two weeks later. Robinson concludes with a plea for more extensive use of this method of treatment in tetanus, and urges that all cases, whether successful or not, be reported.

Experimental Anemia.—C. H. Bunting thinks that pernicious anemia is due to the absorption into the circulation of a substance or substances of hemolytic power toward human red blood cells, and in such amount as to produce not only destruction of circulating red cells, but also destruction of, and injury to, cells of the erythrogenetic groups of the bone marrow. This results in defective and atypical blood formation, partly compensatory, partly the result of injury. In secondary anemias there is a loss or destruction of red blood cells from the action of toxins, but the bone marrow is uninjured and its proliferative power continues until at some time in the disease the toxin may be so increased that the marrow is affected and the anemia takes on the pernicious type. One toxin that will produce the pernicious anemia type is known—that of *Bothriocephalus*—but in most cases we are in ignorance of the nature of the poison. There is a tendency, however, to credit it as coming from the gastrointestinal tract, and Bunting is inclined to think there is much in Hunter's theory which attributes the infection to oral sepsis, and refers to two cases recently observed by himself, in which, together with chronic gastritis, there were dental caries and pyorrhea, and in one of the two, chronic glossitis, and in the other also chronic pathologic alterations of the tongue. The clinical history of remissions and relapses in pernicious anemia suggest that the infection is one that does not confer lasting immunity but may, on the contrary, leave the patient even more susceptible.

The Lancet, July 27, 1907.

The Carriage of Infection by Flies.—R. M. Buchanan presents a communication telling of experiments which conclusively show that flies alighting on any substance containing pathogenic germs are capable of carrying away those organisms in large numbers on their feet and of depositing them in gradually diminishing number on surface after surface with which they come in contact. They further serve to demonstrate the necessity for the exercise of stringent measures to prevent the access of flies to all sources of infection and to protect food of all kinds against flies alighting on it. The diseases which were made the subject of the experiments were typhoid fever, swine fever, staphylococcus abscess, pulmonary tuberculosis, and anthrax.

A New Microscopical Diagnostic Method and Some Simple Methods for Staining Liquid Blood.—Roland Ross, J. E. Salvin-Moore, and C. E. Walker, in a recent publication, showed that certain strings of granules were the remains of the nucleus of the original cell, and called them *chromolinin granulations*. In health they occur in about one per cent. of the corpuscles, but more frequently in a few pathological conditions. Probably the simplest method for demonstrating the granulation is the glass-rod method of liquid staining. A large drop of blood is taken up on a glass slide, and a drop of stain is quickly placed close beside it. The two drops are thoroughly mixed together, and small quantities of the mixture are transplanted on to other slides, where each is covered with a coverslip. A polychrome saturated solution of methylene blue in 0.5 per cent. salt solution should be used. The granules look like small particles of stain adhering to the surface of the corpuscle. True nucleated red corpuscles can be readily distinguished by the fact that the nuclear membrane is still intact. Another procedure is the agar method. Ordinary agar is melted and mixed with filtered saturated solutions of various stains and poured on sloped glass slides. While the agar surface is still moist a coverslip charged with a droplet of blood is dropped upon it. In a few minutes the elements take up the stain, and the centrosomes and chromolinin granulations become apparent. The drained drop method consists in charging a coverslip with a fairly large droplet of blood slightly spread out upon it and then inverted on a shallow cell made with vaseline on a glass slide. This gives the usual hanging drop preparation. They call attention to this phenomenon in the hope that clinicians may find it useful for diagnosis and treatment.

Cerebral Hyperemia as a Factor in the Therapeutic Action of Lumbar Puncture.—Frank C. Eve has, during the past few years, always measured the intracranial pressure during a lumbar puncture, and has been led to the provisional conclusion that relief of tension should be given therapeutic credit only in cases where the hypertension is considerable; and that where the tension is normal or slightly raised the benefit which sometimes results should be ascribed to other causes. These causes may be manifold, but he says he would like to advocate the predominant claims of one factor which has not received attention, a marked passive *hyperemia* of the cerebrospinal vessels which must inevitably result from the removal of any considerable quantity of cerebrospinal fluid. He then cites a case of tetany treated by lumbar puncture. This illustrated that the therapeutic value of lumbar puncture is largely, and sometimes solely, due to the hyperemia produced. He believes, too, that it is a new treatment for rebellious cases of tetany which have resisted all other ordinary methods.

British Medical Journal, July 27, 1907.

Abnormal Fat Assimilation Associated with Some Diseases of the Intestine.—Owen T. Williams presents clinical and chemical observations which tend to show that there are conditions in the intestines in which certain soaps and other insoluble compounds of fatty acids are not absorbed by the intestinal mucous membrane, and that with the presence of these conditions diseases of the alimentary tract are related. The analyses given show that true intestinal sand, appendix concretions, and some bodies formed in the intestines are largely formed of fats and soaps. The fats and soaps present are compounds of saturated

fatty acids. The constitution of these bodies and their relation to each other in chemical constitution throws much light upon the etiology of appendicitis and mucous colitis and possibly upon the underlying factors in certain diseases accompanied by colic.

On the Etiology and Pathological Histology of Beri-Beri.—R. Tanner Hewlett and W. E. De Korte, in concluding their article, as a working hypothesis, suggest that beri-beri is a protozoan infection; that the infecting agent is eliminated in the urine, and that the urine is the source of infection.

Arthritis and Erythema Nodosum.—J. Odery Symes reports three cases to illustrate the fact that not only is it difficult in a large proportion of cases of erythema nodosum to recognize any rheumatic taint, but that even when arthritis is present it may differ very markedly from that found in acute rheumatic fever.

Interstitial Pancreatitis in Its Relation to Sprue.—A. W. Mayor Robson thinks that it is highly probable that some of the cases diagnosed as sprue owe their origin to inflammatory disturbances of the pancreas, and in other cases the pancreatic disease forms an important complication requiring treatment.

Berliner klinische Wochenschrift, July 22, 1907.

The Habitual Vomiting of Infants.—Peiser says that the infants who habitually vomit may be divided into two general classes. The first of these appear to thrive fairly well in spite of the disorder. Some of them indeed may exhibit unusually good development. A large number of these children are breast-fed and the condition frequently depends on irregular feeding at too short intervals. On regulating the hours of nursing the vomiting stops promptly. In another group the vomiting is the result of a milk that is too rich in fat and treatment must be directed toward diminishing this constituent either by reducing the size of the meals, by removing some of the fat from the milk, or most simply, by reducing the total daily amount, by lengthening the interval between meals. Another group belonging to the first class consists of the neuropathic children who are always restless, sleep badly, are subject to laryngismus stridulus, and are hard to manage. The treatment of these cases is difficult, but the symptoms ordinarily disappear on weaning. Children belonging to the second class are apt to be undernourished and possess flabby muscles with much reduced gastric motility. Their vomiting is more in the nature of regurgitation, and they ordinarily manifest the symptom only if disturbed after meals. As the result of x-ray observations of the stomachs of such children the author has come to the conclusion that owing to the universal muscular relaxation the cardia is incompetent and through the lessened motility the food remains a long time in the stomach and is thus easily forced up into the esophagus. The treatment of these children is mainly constitutional and should be directed toward an improvement in their general condition. The author leaves out of account the typical and well characterized cases of pyloric stenosis, but describes one unusual case which came to operation. This infant's abdominal cavity was found to exhibit exceedingly numerous adhesions binding together the coils of intestine and probably resulting from a fetal peritonitis.

Localized Adhesive Cerebral Arachnitis.—Placzek and Krause apply this term to a condition discovered at an operation performed on a woman of twenty-five years for what was supposed to be a tumor of the posterior cerebral fossa. No new growth could be discovered in spite of the fact that the technique employed by Krause permits very extensive inspection of the cerebellum and base of the brain, but there was found a considerable accumulation of fluid forming a cyst-like swelling over the lower part of the cerebellum and apparently due to distention of the meshes of the arachnoid with fluid. The patient recovered completely, though a singular complication was the long persistence after the operation of irregular elevations of temperature, which in the absence of all other explanations were ascribed by the authors to disturbances of the heat regulating center occasioned by the manipulations in the posterior fossa.

Munchener medizinische Wochenschrift, July 16, 1907.

The Constipating Action of Morphine.—Magnus describes observations on the effect of morphine on the intestinal tract. These were made mainly on cats, though some dogs were also used. Nothnagel maintained that therapeutic doses of morphine stimulated the splanchnic inhibitory fibers and in this way checked intestinal motility. Some observers have agreed with this view, others have opposed it, but most of them have regarded the small intestine as the chief site of the morphine action. Magnus found by means of radiographic observations on cats in whom diarrhea had been induced by milk diet that it is the stomach that is most affected by the alkaloid. The constipating effect is not produced through the sympathetic inhibitory fibers, for section of these in the experiment animals did not modify the results. The chief action of the morphine consisted in a persistent contraction of the stomach wall in the neighborhood of the so-called sphincter of the pyloric antrum. At the same time the pylorus retarded the passage of the food into the duodenum so that it entered the small intestine much belated and then only very slowly and in small portions that were more fully digested than usual. The small intestine was but slightly affected and the colon least of all. The author reminds the reader that these results as yet apply only to the two varieties of animals experimented on and suggests careful clinical observations with a view to estimating the fidelity with which the conditions in man are reproduced in the animals.

The Results of Pessary Treatment in Gynecology.—Schwab says that although the treatment of gynecological conditions by means of pessaries is usually passed over very lightly or ignored altogether in the text-books of the subject, appliances of this sort are still very widely used in general practice. In order to get some idea as to the actual utility of the instrument he collected records of 124 cases in which the pessary had been used in the university clinic at Erlangen. Seventy-three of the 124 patients received their pessary treatment in the clinic, whereas the other 51 had been treated in this way by previous physicians. Those subjected to the pessary in the clinic were all patients for whom operation was inadvisable for one reason or another, and the results were satisfactory in less than half of the number. Of the 51 patients who had been fitted with pessaries outside practically none had been benefited. The author considers that while the value of the instrument when applied by the specialist is comparatively slight, when used by the average practitioner it is of practically no use at all.

Deutsche medizinische Wochenschrift, July 18, 1907.

A Case of Banti's Disease Cured by Operation.—Caro describes this unusual case. The patient was a man of thirty years who was in an extremely precarious condition when he came under observation. The abdomen was distended with fluid, which rapidly recurred after tapping, and the spleen was much enlarged, the liver was not palpable, and there was gastric achylia. The hemoglobin was 35 per cent., the red blood cells were 1,400,000, leucocytes 2,600, of which 60 per cent. were polynuclears. As a last resort splenectomy was decided on and was successfully carried out. The patient's temperature remained high during the four weeks following the operation, but aside from this the recovery was uncomplicated. A year later the hemoglobin was 80 per cent. and the red cells 400,000. There was no ascites and no subjective symptoms. The author regards the postoperative temperature as evidence of the toxic or infectious nature of the disease.

A New Method of Testing the Motility of the Stomach.—Strauss and Leva say that all the methods that have so far been suggested for the purpose of investigating the motility of the stomach are open to objections of one sort or another. They consider it as a desideratum that both the secretory function and the motility be tested with the same test meal. Sahli's method in which the portion of the test meal retained is estimated by determining the amount of fat present in the stomach contents at a specified time after the ingestion of a specially prepared soup composed of flour and butter has many advantages, but is open to the drawback that the patient is required to take a separate test meal for this purpose. The authors have devised a method which is intended to permit of ascertaining information of both kinds from a single meal. For this purpose a particular kind of zwieback containing about 5 g. of butter to 50 g. of the finished product is used. The test meal consists of 50 g. of the zwieback and 400 c.c. of tea, an hour later the stomach contents is removed. The organ is washed with 100 c.c. of warm water and this result is considered as specimen number 2. Finally the stomach is washed out with a sufficient quantity of water to effect complete cleansing, and this is marked portion three. Portions one and two are used for the purpose of making any desired tests in regard to the secretory function, and then all three specimens are evaporated on a water bath and their fat content is determined by means of the refractometer. The authors consider the latter an essential feature of the method and give detailed instructions for the use of the instrument.

French and Italian Journals.

Neurasthenic Syndrome from Insufficiency of the Salivary Glands.—U. Baccarani contributes to the study of the internal secretion of the salivary glands. In former

researches he demonstrated that two new functions of the salivary glands should be recognized, an antitoxic function in the sense of contributing with other organs to the protection against poisoning of the organism, and one of internal secretion. He reports three observations of patients in confirmation of his statements, resulting from experiments in the laboratory. In three persons the author observed a syndrome of muscular and nervous asthenia with slight loss of flesh, which disappeared in two weeks after the reestablishment of the salivary secretion. He interprets these symptoms in conjunction with the experiments already made as resulting from the absence of the salivary secretion. Zagari has reported a case of absence of salivary secretion due to atrophy of the salivary glands, in which death ensued in a state of marasmus. In others there appears an exaggerated neurasthenic condition as a result of paresis or paralysis of the salivary function.—*La Riforma Medica*, March 30, 1907.

Diagnosis of Late Hereditary Syphilis.—L. Landouzy says that in some way the effects of syphilis are evident in two-thirds of the patients seen at hospitals. The method by which we cannot miss making the diagnosis is that of a systematic examination of the patient's history, his bodily condition, and the condition of the other members of his family, including collateral branches. Study the physiognomy and appearance of the patient first, looking for dystrophies. The stigmata of the habitus have the greater diagnostic importance. Then come infantilism, early obesity, cranial, facial, ocular, and dental manifestations of syphilis. There are many changes in the shape of the bones of the skull. There are changes in the skin and mucous membranes, testicular and nervous stigmata, such as absence of reflexes, tic, epilepsy, tabes, intellectual and moral lack of development; there are diathetic conditions, hemoglobinuria, bradytrophies, failure of growth, visceral conditions, cardiovascular, and cerebrospinal affections that are congenital. The discovery of such stigmata alone or combined in a patient may be confirmed by examination of other members of the patient's family. These persons should be seen and examined. Factors of importance are infantile polymortality, abortions, twin pregnancies. All these conditions will be of diagnostic value.—*La Presse Médicale*, April 10, 1907.

Treatment of Chronic Coryza in Scrofulous Children at Borboule.—E. F. Christin eulogizes the value of the warm arsenical waters of Borboule, France, in those cases of children, from the ages of five to fifteen years, who present a pale, flabby condition generally, accompanied by a mucopurulent catarrh of the nasopharynx. This causes them to swallow pus continually while it runs over the lip. The cause of this condition is one of bad general condition rather than local lesion. Examination shows mucopus in the anterior nasal space, with an atrophied condition of the mucous membranes, while in the post-nasal space there are pale, flabby growths and traces of operations, with Luscha's tonsil ridged and the hollows filled with mucopus. The elevated situation and protected valley at Borboule, with its southern exposure, is of great benefit to these patients from a climatic point of view. The warm arsenical waters may be used directly from the pipes as nasal douches. There is a congestion of the mucous membranes produced, which causes increased capillary circulation, and phagocytic reaction. The swollen glands are reduced, and the general and local conditions are improved.—*Le Progrès Médical*, March 23, 1907.

Bier's Stasis Method in Osteomyelitis and Tuberculous Osteoarthritis.—Tammaso Costa has found that the stasis method of Bier as applied to tuberculous joints is not a success, and even results in the destruction of tissues that could be useful in an operation for excision. He concludes that in tuberculous ostitis and osteomyelitis with large loss of tissue and communications of the joint with the external air the method produces no benefit and should be avoided. It has some beneficial effect in postoperative cases. The passive hyperemia is of much value in closed osteoarthritis, and has produced excellent results, especially when combined with other therapeutic methods.—*Giornale Internazionale delle Scienze Mediche*, May 31, 1907.

Hemorrhages and Coagulation Diseases of the Blood.—P. Emile Weil and Octave Claude say that hemorrhages constitute a frequent symptom of nephritis, but the cause of these hemorrhages has not been thoroughly studied. They occur in both acute and chronic forms of nephritis. In the acute form blood in the urine is generally the symptom noticed, while in the chronic forms there are epistaxis, cerebral hemorrhages, retinal hemorrhages, and purpura hemorrhagica. The author believes that difference in the coagulating power of the blood, slight or severe, accounts for these hemorrhages. Their frequency is great, although the coagulation goes unnoticed. The treatment to arrest these hemorrhages consists of subcutaneous or intravenous injections of fresh serum, and the use of such serum will give excellent results. The original cause of the lack of coagulation may be toxoinfectious, or due to marked congestion. The author describes four cases illustrative of these statements.—*La Tribune Médicale*, April 20, 1907.

Remote Results of Treatment of Cancer of the Breast; Prognosis; Statistics of Fifty Cases.—E. Villard and E. Mouriquand give the statistical report derived from fifty cases treated in the service of Villard. In all the cases a racquet shaped incision was made, amputation of the entire breast was done outside the limits of the tumor, with a systematic excision of the subjacent aponeurosis when the tumor was adherent to it, removal of the pectoral muscles and other tissues down to the chest walls, and removal in mass of the axillary glands and adipose tissue. Following the operation some patients were submitted to radiotherapy. These were all undoubted cases of cancer, and all but twelve were confirmed by examination of removed tissues. Of these fifty patients twenty-two are living without recurrence, five are living with recurrences that have been treated by radiotherapy, and are probably cured. The cases are now from eighteen months to eleven years from the time of operation. In twenty-eight cases the glands were examined; fourteen were normal, fourteen cancerous. Thirteen of these are cured. The prognosis of cases in which glands are involved is bad. The *x*-rays have reduced the tumors in size and shown destructive action on the cellular elements. In some cases the rays have shown themselves as causes of serious accidents, causing a severe glandular reaction which renders their action dangerous. The treatment sterilizes the tissues after operation and here they are very useful. The authors conclude that cancer may be cured by early operation in a large number of cases, especially when the glands are not involved. Any tumor of the breast after the age of thirty should be removed.—*Lyons Médical*, May 19, 1907.

Suppurative Mammitis After Typhoid.—Henri Roger describes the case of a young woman attacked with typhoid fever and convalescing in whom the left breast gradually underwent abscess formation without pain and with a very slight elevation of temperature. After opening the abscess it healed rapidly. On examination of the pus from the abscess it was found that the bacillus present resembled most the paratyphoid bacillus. In this case the typhoid intoxication had been very severe, characterized by vomiting, myocarditis, and dyspnea of bulbar origin with cyanosis. Only twenty-four cases of mammitis after typhoid can be found in literature. It appears at the end of the disease and with slight elevation of temperature. As soon as the collection of pus has been incised it heals. Previous lactation with its attendant congestion favors this complication. Of the cases in which the pus was examined two contained *Staphylococcus aureus*, one *Staphylococcus albus*, two the bacillus of Eberth, and one the paratyphoid bacillus. Hence the cause of the complication is not always the same.—*Gazette des Hôpitaux*, May 18, 1907.

Pulsating Points in the Diagnosis of Arteriosclerosis.—Leone Minervini goes over the etiological factors in the production of arteriosclerosis, the cerebral tension, degenerations as a result of intoxications, and infectious diseases being the principal ones. The arterial changes may appear in the heart, liver, kidneys, spinal medulla, brain, or peripheral vessels. An early diagnosis is most important, since there is a presclerotic state that may be recognized, and the causes eliminated by individual and social prophylaxis. The general arterial condition is shown by the tone of the vessels, character of the pulse, and auscultation of the aorta. The principal signs are instability of the pulse, digitocapillary sign, sphygmographic tracings, accentuation of the second aortic sound, systolic bruit over the aorta, with a hard but not small pulse, slightly retarded, systolic silence over the aorta, doubled first aortic sound, intermittent claudication, vertigo, cerebral symptoms, pericorneal ring, spinal symptoms, premature senility, radial rigidity, and pulsating points over the radial and other arteries. The author occupies himself especially with the pulsating points. Those of the radial are three, at the division of the humoral artery into the radial and the cubital, at the junction of the upper and middle thirds of the radial artery, where it ceases to be oblique, and at the pulse point. There are important pulsation points also in the jugular fossa, over the carotid, in the omohyoid (triangle, subclavian, axillary, humeral, femoral, and popliteal regions. Visible arterial pulsation is due to four factors: Increased cardiac contraction, increased distension of the arteries due to decreased aortic tension, greater expansion, and rapid pulsation. These points do not pulsate in the normal man. By the number and force of the pulsating points we may be assisted in the prognosis of the cardionathy.—*Giornale Internazionale delle Scienze Mediche*, March 15, 1907

Book Reviews.

A Practitioner's Handbook of Materia Medica and Therapeutics. Based Upon Established Physiological Actions and the Indications in Small Doses. To which is Added Some Pharmaceutical Data and the Most Important Therapeutic Developments of Sectarian Medicine as Explained Along Rational Lines. By Thos. S. Blair, M.D., Member American Medical Association, Pennsylvania State Medical Society, Harrisburg Academy of Medicine, etc. Philadelphia: The Medical Council.

This volume contains in small compass what the author considers of most value in the Materia Medica of all schools. In many instances all three schools agree upon the indications; and where such agreement is not obvious, divergent views have been carefully considered, and preference given to such data as show the greatest physiological, chemical, and clinical foundation. Purely theoretical discussions are avoided. The book appears to be written in a fair and impartial spirit, and while not designed to replace the larger works on the subject, it will form a useful and handy supplement to any of them.

Le Cerveau et la Moelle Épinière, avec Applications Physiologiques et Medico-Chirurgicales. Par Ch. Debierre, Professeur d'Anatoime à l'Université de Lille; Membre correspondant de l'Académie de Médecine et de la Société de Biologie. Avec 373 figures en noir et en couleurs dans le texte et 14 planches hors texte. Paris: Felix Alcan, 1907.

Such great advance in the knowledge of the anatomy and physiology of the central nervous system has been made in comparatively recent years, and so many theories promulgated, that an occasional new book by a competent authority, bringing us up to date, is welcomed, and when such a book combines physiological function with anatomical description, we who have passed through the mill of learning histological nervous anatomy at the start, without it, can still further appreciate the book. The physician will find the work convenient for reference in diagnosis, and to refresh his memory; and the surgeon, who is becoming more and more bold and self-feliant, in brain and cord surgery, will note many drawings and illustrations, as well as descriptions, that should be of assistance to him. The scope of the work takes in the gross and microscopic anatomy of the brain and cord, with descriptions of the functions of various parts, in health, and as modified in pathological conditions. The book is profusely illustrated.

Opuscula Selecta Neerlandicorum de Arte Medica. Fasciculus Primus quem Curatores Miscellaneorum quae vocantur Nederl andsch Tijdschrift voor Geneeskunde Collegerunt et Ediderunt und celebrandam Seriem Quinquagesimam in Lucem Nuper Editam. Amstelodami: Apud F. van Rossen, MCMVII.

In order to commemorate the fiftieth anniversary of the foundation of the Nederlandsch Tijdschrift voor geneeskunde, its editors and publishers decided to issue a volume containing noteworthy contributions to medical literature by eminent Dutch scientists. The present volume is the outcome of this project and is made up of addresses or essays by six authors. The first is a lecture by Erasmus in praise of the art of medicine; the second a letter written by van Leeuwenhock to the Royal Society of London and describing the circulation in the tadpole and small fish; the third observations in the muscles of the frog by Swammerdam; the fourth an address by Boerhaave on the mechanical method in medicine; the fifth an inaugural address by Gaubius, in which it is shown that chemistry should be classed among the academic sciences; and lastly an address by Donders on the harmony existing in animal life. These dissertations are printed on one page in their original Latin or Dutch and on the opposite page is a translation into English, French, or German. Very artistic reproductions of the portraits of these worthies, including the well-known Dürer portrait of Erasmus, preface each section of the book, and reproductions of some of the old wood cuts used by the authors are also included. Altogether the volume represents a happy conception exceedingly well carried out.

Wellcome's Photographic Exposure Record and Diary. 1907: Burroughs Wellcome & Co., London, Eng.; New York, Montreal, Sydney, Cape Town. New York offices, 45 Lafayette street.

British photographers have long appreciated the utility of this well arranged pocket book, and no doubt the edition modified to suit the requirements of workers in this country will prove equally popular. In addition to the pages arranged for the reception of the photographer's field notes and dark-room records, a great deal of useful information is given in regard to methods, formulas, etc., and a very ingenious exposure meter, which gives the required length of exposure by one setting, is affixed to the back cover. The number of physicians who practice photography not only for pleasure but also as an important adjunct to their system of case records, is rapidly growing, and this little volume may be commended to their attention.

Makers of Modern Medicine. By James J. Walsh, M.D., LL.D., Acting Dean and Professor of the History of Medicine and of Nervous Diseases, Fordham University Medical School, and Adjunct Professor of Medicine at the New York Polyclinic School for Graduates in Medicine; Professor of Physiological Psychology at St. Francis Xavier's College in New York. New York: Fordham University Press, 1907.

There are no more fascinating biographies than those of the leaders in medical science, and Dr. Walsh has in this volume chronicled the lives of some of the worthiest in the annals of the history of medicine. In accordance with the plan of the volume, which is to trace the development of the science and art as we of to-day know it, the author has begun his work with what may be termed the renaissance period of medical history, and the first biography is that of Morgagni, the father of pathology. The essays that follow are on Auenbrugger, Jenner, Galvani, Laennec, Graves, Stokes, Corrigan, Müller, Schwann, Claude, Bernard, Pasteur, O'Dwyer. While this list is not above criticism it is a fairly representative one, and at any rate the life histories are agreeably told and hold the reader's attention. To some the author's ecclesiastical divagations may seem unnecessarily numerous, but this again is a matter of personal opinion and the book is a pleasing addition to the all too limited field of medical *belles lettres*.

Diseases of the Lungs. Designed to be a practical presentation of the subject for the use of students and practitioners of medicine by Robert H. Babcock, M.D., Author of "diseases of the Heart and Arterial System." Until recently Professor of Clinical Medicine and Diseases of the Chest, College of Physicians and Surgeons (Medical Department of the Illinois State University), Chicago; Consulting Physician to Cook County Hospital; Consulting Physician to Mary Thompson Hospital, Hospital of St. Anthony de Padua, and of Marion-Sims Sanitarium; Fellow and Former President of the American Climatological Association; Fellow of the Association of American Physicians; Corresponding Member of the Medico-Chirurgical Society of Edinburgh and of the International Tuberculosis Institute, etc. New York and London: D. Appleton & Co., 1907.

In view of the many excellent treatises on diseases of the chest which have appeared within the last five years, it requires no little confidence, not to say temerity, on the part of an author to add another volume on diseases of the lungs to the already prolific literature. Nevertheless Dr. Babcock's long practical experience justifies the publication of the present volume which, while presenting nothing that is particularly new in the diagnosis or treatment of pulmonary diseases, is replete with excellent chapters on such subjects as can never become trite to the student of medicine. The five opening chapters on the various forms of bronchitis and the respective treatment of each are clear and forceful. Naturally the most important feature of the work is that which deals with the subject of tuberculosis, upon which there are eight chapters. Here, as elsewhere, the author has drawn largely from personal experience, and the work is replete with illustrative cases. In fact, clinical phases predominate throughout the book, perhaps somewhat at the cost of the pathological aspects. To the all-important subject of pneumonia the author has devoted six chapters, covering the subject satisfactorily and in an especially commendable manner in the case of acute fibrinous pneumonia. The three concluding chapters of the work are devoted to diseases of the pleura, a subject which the author has perhaps treated less exhaustively than might be desired. The work is well illustrated and excellently indexed.

Notes on Blood-Serum Therapy, Preventive Inoculation and Toxin and Serum Diagnosis for Veterinary Practitioners and Students. By Walter Jowett, F.R.C.V.S., D.V.H., Formerly Demonstrator of Comparative Pathology and Bacteriology in the University of Liverpool. Chicago: W. T. Keener & Co., 1907.

This book contains a short account of the subject of immunity, and the vaccines, sera, and toxins used in present day veterinary practice for the prevention, treatment, and diagnosis of disease. The first chapter is an excellent *résumé* of the subject of immunity; it also explains Wright's opsonic theory, agglutination and precipitation. The remainder of the book deals with the application of the subject to veterinary practice.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-fifth Annual Meeting, Held at Exeter, July 27 to August 2, 1907.

PRESIDENT, RICHARD ANDREWS REEVE, B.A., M.D., LL.D., TORONTO.

PRESIDENT-ELECT, HENRY DAVY, M.D., F.R.C.P., EXETER.

(Special Report to the MEDICAL RECORD.

GENERAL MEETINGS.

THE earlier days of the week were occupied only with the general meetings and official business, so that it was not until Wednesday that the sections opened and scientific work began in earnest. On Tuesday, however, the introduction of the new President, Dr. Henry Davy, F.R.C.P., took place with the usual ceremony, and in the evening he delivered his address.

President's Address.*—Dr. HENRY DAVY, after some introductory remarks of welcome and a brief sketch of the secular and medical history of the City of Exeter, said that he desired to invite the attention of the members of the association to a consideration of some of the ways in which the important advances in science might be applied to the furtherance of national health. He began by saying that the most important function of the medical profession was the practical application of the science of their day to the health and life of the individual, and through him to the community, and our success and usefulness depended on the truth and the value of the knowledge which the science of the day has reached. In earlier times there was very little in the knowledge of the day of which medical men could avail themselves usefully to explain or to combat disease, and the place of true scientific knowledge was occupied by more or less inaccurate theories as to the causes and the best way of treatment of the various diseases. In considering the changes which have taken place in medical knowledge and treatment, we had to remember that the knowledge which we use in the profession of medicine was of two kinds—empirical and scientific, using these terms in their highest sense. Each of these systems was of great importance. Much of the best information about disease, and many of the most useful plans for its treatment, had been handed down to us from remote ages as the product of experience and observation, and was thus truly "empirical"; and a large part of the empirical observation of the early forties was as good to-day as it was then. The knowledge which we called scientific—that gained by systematic experiment and reasoning—was of even more importance; in fact, when founded upon proved truth it was all-important, and it was the possession of such accurate and true knowledge that distinguishes the medicine of to-day from the medicine of the early forties. One of the greatest events which had happened in the last sixty-five years had been the promulgation of the Darwinian theory. The speaker considered that the importance of this theory had not as yet been sufficiently recognized by the public at large, and that the lessons to be drawn from it had not been sufficiently insisted upon. It had hitherto been used and discussed as though it explained or did not explain the creation of the world and man, and it had been examined and reexamined from this aspect, with very little benefit to any one. Nevertheless, Darwin's work had a great meaning for our profession, for his demonstration "that the only way to maintain any organ or structure of the body in its proper condition of health and development is by a proper and adequate use of it" was the great scientific keynote of health in every department of life, while his statement that "in the struggle for existence the fittest will survive" seemed to be as entirely a law of Nature as Newton's law of universal gravitation. But, if the survival of the fittest in the struggle for existence were true, then it followed that in this struggle the healthiest must be the fittest. It would be well if in these days people could be made to understand thoroughly that the cultivation of health was the first necessity of useful lives, and, if they strove to attain it, as the first object of their solicitude; if they recollected that the chief and best asset of a nation was the number of healthy individuals it contained, and if they would also recognize the great principle that no educational system was good which did not aim at producing well-developed, healthy bodies as well as well-trained minds. The speaker quoted several passages from the writings of Carlyle in this connection, and went on to discuss the question of health. This, he said, involved harmony—the actions of all the parts of the body perfectly adjusted to each other in order to produce this effect, and our work as medical men often was to bring about this necessary adjustment. In considering all questions of health it was necessary, however, to think of not only the individual patient, but also of his environment, meaning by this the sum total of influences which modify and determine the development of his life and character. This question of "environment" had of late years come very much to the front with regard to the question of physical deterioration of the nation as illustrated by the number of would-be recruits for the army, who were found to be so physically undeveloped that they did not come up to the requisite standard. In this connection he asked attention to one or two points that illustrated the scientific teachings we had gained since the middle of the last century. Darwin shows "that the only way to keep any organ or structure in health is by proper and adequate use thereof," and the value of this axiom had not been sufficiently recognized in considering the question of physical deterioration and its remedy, especially as it affected the muscular system; for many changes had taken place in the environment of the individual and of the nation, all tending to reduce the muscular work done by the people, and in advance of everything else which had effected this result the speaker placed the extended use of machinery. In every department of work, in every trade and business, each succeeding year found us depending more and more on "labor-saving machines," every new machine tending more and more to replace muscular work, until at last in some manufactures the operative had little or no work for his muscles to do except just attending to the machine, driven by steam or electricity, by which all the work which used to be the result of his muscular activity is now accomplished. But, in addition to the development of machinery, many other causes had contributed to the same end. The nation had become much more urban than it used to be. Villages and country towns, with all their facilities for healthy muscular work in the open air, had diminished; big centers of trade and manufactures had increased in population; railroads had extended networks of lines in every direction, so that traveling was made easy without any exertion, and the inhabitants of our towns had in addition tramways and omnibuses to take them from their houses to their work, without the necessity of even the exercise of a long walk. Habits also had changed and athletic games were less often indulged in, and in consequence disorders of metabolism resulted. It was something of a reflection on our profession that we often treated patients with drugs who needed more exercise and less food. Physical culture was one of the most pressing questions of the day, for

*Abstracts of the President's Address and of the Addresses in Medicine and in Surgery were made from advance sheets received through the courtesy of the Editor of the *British Medical Journal.*

it was by it alone that we had a proper remedy for the state of muscular degeneration which was so prevalent. It ought to be considered by every educational authority, for by its use dwellers in city and country alike could have their muscular systems built up and developed to a healthy standard. He then spoke of the great importance of medical supervision of school children, and stated that every school in the country, without exception, should be under the supervision of a properly trained medical officer. It should be his duty, with his assistants, to examine every pupil, to see who are healthy and who are diseased, who are fit for a course of physical culture and who are not, and generally to look after the health and development of the children. How necessary such medical supervision must be is proved by the fact that Dr. Alfred Greenwood, Medical Officer of Health for Blackburn, in an examination of 388 school children of that town, found that no less than 54 children were affected with some form of tuberculosis, and of this number 34 had tuberculosis of one or both lungs. A very essential feature of the supervision of the schools was the proper physical training of the children by suitable out-of-door games and sports. Next to this question of physical culture, and of equal importance, was that of the feeding of the people, and it was one of the problems on which we, as teachers of the science of our day, ought to have much to say. In the consideration of this question of food, the fads and fancies of various more or less eminent individuals had been allowed far too much prominence, so that the scientific principles which should guide the people to a sensible and right conclusion had been entirely obscured, and the opinions expressed have sometimes brought the whole subject under ridicule. We must remember that food could never be served out by weight, and that, provided the average amount of the various elements of food was kept fairly well within the scientific limits required of them, no great harm would be done to health by non-insistence on fractional details. We must also realize that the feeding of civilized man was not merely a question of "stoking the engines" of the body, and that no harm was done to the system by cooking the food in a tempting and pleasant way, provided the scientific amounts of food be not greatly exceeded. The exquisitely cooked food of a first-class chef was far more digestible and healthful than the same food unappetizingly cooked by an ignorant general servant. In conclusion he spoke of the great reduction in mortality from pyemia and typhoid fever that had been effected by the modern methods of education and sanitation, and expressed the conviction that similar measures were necessary in order to check the prevalence of tuberculosis. This subject he considered as urgently demanding appropriate legislation.

As a part of the ceremony of induction the vote of thanks to the retiring president, Dr. R. A. Reeve of Toronto, was carried amidst great applause and excited more than usual interest, especially as he was present and replied in person. He said much of the credit of the success of the Toronto meeting which had been so cordially referred to by the proposer of the vote was due to the loyal and united efforts of those who acted on the various committees.

Dr. Deas, president of the local branch of the British Medical Association, then, in a brief speech, referred to the "Book of the Southwest," which had been distributed as a guide to the members and which was a step in advance of previous issues of the kind, as it constituted a guide-book to the city and district, the scenery, the climate, and other points of interest. A copy, with an inscription, form[illegible] handed to the president by the speaker, elicited another pleasant speech acknowledging the unexpected compliment.

It was then decided to hold the next meeting at Sheffield and Mr. Simeon Snell was unanimously appointed president-elect. The financial statement next occupied the meeting and a new treasurer was appointed to succeed Dr. Crocker, who had resigned.

The Middlemore prize was presented to Mr. Sydney Stephenson, M.B. The report of the Council was adopted. The representative meeting also occupied much time, and many questions of importance as to organization, the reports of committees, and general official business, were discussed, but these were of interest chiefly, if not altogether, to the profession at home.

By Wednesday, when scientific work began in the sections, some 900 members had put in an appearance. On the afternoon of this day the address on medicine was delivered by Dr. Hale White of Guy's Hospital, but the fine weather induced the majority of members to take advantage of the many outdoor events provided for their amusement, and the attendance suffered in consequence.

Address in Medicine.—Dr. W. Hale White, in this address, said that while no one else felt a greater pride in his profession than himself, he did not intend to discuss the advances that had been made, but to indicate some ways by which he believed that the solution of many of the problems of the science could be expedited. Before commencing to speak of some of the directions in which we could help ourselves by greater accuracy of thought when attacking medical problems, he wished to beg his hearers to take all possible opportunities of bringing before the public the duty they owe to medicine. Those who do that successfully do, indeed, help the profession. We and our allies working at physiology and pathology were constantly trying our hardest to diminish suffering and get rid of disease, yet we received little help from the very public whose suffering we were endeavoring to lessen. There ought to be fully-endowed professorships for teaching and research, so that those having a taste and ability for such work might do it, and not, as now, have to pass it by because they could not earn their bread and butter by it. A little had been done by a very few wealthy, far-seeing, generous donors, and all of us, both public and doctors, were grateful to them, but to show how much more help is needed it was only necessary to mention that in London not a single medical school had a fully-endowed professorship of pathology. He then continued by expressing the fear that the progress of science was retarded by our being afraid to say we do not know. The desire for explanations was not always beneficial, since wrong explanations might be worse than none, as many people accepted them comfortably without stopping to inquire if they were reasonable, but if no explanation were in the field thinkers would devote themselves to the problem which they now pass by, being soothed by the current false interpretation. He took gout as an illustration of this and said that accumulated observation and experience had taught us a great deal about gout, but all we really knew of its pathology was that urate of sodium is deposited in some cartilages and other structures, and that there is an excess of uric acid in the blood. Nevertheless, often, instead of boldly saying to ourselves we do not know the cause of many cases of neuralgia, sciatica, bronchitis, and several other diseases, we set them down to gout: but where were the figures from the post-mortem room showing that urate of sodium is excessively frequently found in the cartilages or fibrous structures of, for example, people suffering from sciatica, or that they have an excess of uric acid in their blood? If we thought accurately, we ought not to say a person had gouty sciatica unless we believed that he had urate of sodium in some of his cartilaginous or fibrous structures, or an excess of uric acid in his blood, and that these facts were etiologically related to his sciatica; further, we ought, as a result of the experience of ourselves or others in the post-mortem

room, to have such good evidence in support of our belief that we should not feel our reputation for skill in diagnosis seriously damaged if the patient were killed on the spot and no urate of sodium or excess of uric acid was found. Some, perhaps feeling the impropriety of calling these conditions gouty on such slender evidence as others deem sufficient, and yet susceptible to the Mesopotamia-like soothing influence of words, irrespective of their meaning, had said: "Here are a number of symptoms we cannot explain. We do not think they are due to gout; but let us imagine that the gout is irregular, or atonic, or undeveloped, or suppressed, and then we can ascribe them to it." In passing, the thought arose, If gout is undeveloped or suppressed, how can it cause symptoms? This method of nomenclature was worthy of Gilbert and Sullivan; but, seriously, is it creditable? Other loose conceptions were those regarding the excess of uric acid in the blood and the dietary restrictions imposed on gouty persons, such, for example, as the injunction to eat no red meat and to take white in its stead. Another instance of our accepting an explanation that had nothing to support it was in making the diagnosis of "hepatic dyspepsia" in certain cases of indigestion. The liver might be almost destroyed by new growth or abscess and yet none of these symptoms arise, they had never been produced experimentally as a result of interference with the liver, there was no constant appearance in the liver after death when these symptoms had been present during life, and it had been shown that the so-called cholagogue drugs which experience has taught us benefit these symptoms have no effect on the secretion of bile. The diagnosis of gastric ulcer also was made much more frequently than the facts warrant, and it was gradually coming to be recognized that there is a condition, to which the term "gastrostaxis" has been applied, in which blood oozes from the gastric mucous membrane without ulceration, and that this is commoner in women than in men. The so-called selected action of alcohol on certain tissues, and the diagnosis of lesions of the heart muscle that did not in reality exist were further examples of lack of accuracy in expression or thought. An important instance of the same thing was the abuse of figures, as if there were no science of statistics. Frequently the mistake was made of dealing with far too few figures; often the very data were wrong; allowance was rarely made for the number of persons alive at different ages; it was very common to see figures published believed to prove the effect of this or that treatment, without any allusion to the rapidity of recovery if no treatment had been adopted, and often figures did not tell us what we desired to know. For example, statistics were published showing the frequency of recovery after some difficult operation. In the first place, for these to be of any practical use we want to be able to contrast them with figures showing the mortality among those not submitted to operation. Next, we ought to compare the expectancy of life among those who are not operated upon with that of those who submit to operation, for it was clear that if the operation considerably shortened the life of many, the total harm done by the operation might be more than the total good. Then, again, although it was interesting to know the degree of perfection to which any particular surgeon could carry the difficult art of operating, and so lower the mortality, yet, as all the patients could not possibly go to the one skillful man, it was far more important to know the usual mortality among operating surgeons. A good illustration of the extreme difficulty of dealing with medical statistical problems was the question whether tuberculous disease is hereditary, or, as we should now say, whether the children of tuberculous parents inherit any special liability to infection by the tubercle bacillus. Many papers had been written on this subject, but hardly any were free from fallacy; some were so full of errors that they were quite valueless. In closing, the speaker said that another hindrance to the advance of medical knowledge was the acceptance of facts upon authority. The speaker would say to all but the youngest students: Accept nothing on authority, but look for yourselves and see if the usual teaching is true; believe nothing you do not see, be skeptical about everything you are told. He did not mean that no respect should be paid to the experience of skilled clinical or pathological observers or experimental pathologists, but all of us should be always on the alert to see if they were correct, and we should respect those who were. Much of the excessive zeal for treatment by drugs arose not only from an unwise adhesion to so-called authority, but from a lack of appreciation that pathology is the basis of all medicine. The primary duty of a physician was to find out what was the matter with his patient, proper treatment could only be secondary to that; all treatment apart from a correct diagnosis, which in most cases should include a correct visual impression of the way in which the body was disordered, was bad, and might well lead to more harm than good. The last point to which he wished to draw the attention of his hearers was that it usually required considerable trouble to train ourselves to receive new ideas properly and by failing in this respect we retarded the progress of medical thought. In this matter there were two chief kinds of mind. Those having the one usually claimed that they were critical, but they were obstructive rather than fair critics. For the most part they were extremely slow to assimilate anything new, strange to say they frequently prided themselves on this and took great comfort from the sad fact that many suggestions which when first promulgated appeared fruitful have turned out to be barren. Those having the other were easily enticed away by new notions just because they were new, they absorbed new ideas too rapidly without digesting them, in popular language they were ready to swallow anything. Fortunately, our profession contained many who fell into neither of these classes, because they had an evenly balanced mind trained to estimate the value of novel suggestions.

Thursday opened with the temperance breakfast, which has now for many years been provided by the National Temperance League, and which always attracts a good number of guests and elicits some able speeches.

In the afternoon came the address in surgery by Mr. Trentham Butlin, who devoted it to cancer, on which he is so distinguished an authority, dealing especially with the question of contagion and autoinfection.

The Address in Surgery.—Mr. Henry Trentham Butlin chose as the subject of his address "The Contagion of Cancer in Human Beings; Autoinoculation." The reason for the difference of views regarding the contagion of cancer lay in the fact that, regarding this as regarding most theories and events, there were two kinds of evidence—that which satisfied the inquirer who wished to believe and that which was required by the skeptic. If the occurrence of cancer in a man and his wife who lived in the same rooms were accepted as evidence of the contagion of cancer, whether the two were affected at the same time or years apart, whether the cancer of the one was of the same kind as the cancer of the other, whether the cancer was exposed or covered, then the case of contagion was not difficult to prove. And of such a kind, for the most part, was the evidence which is adduced to prove the case. Certain conditions of cancer which were quite well known should be actively before the mind of him who investigated this subject. Thus, two or more cancers might occur in the same individual. It was a matter of common observation that several rodent ulcers might attack the face, but no direct relation could be traced between them. In like manner, the surface of the tongue might present two or more squamous carcinomata. Or an individual might suffer from squamous carcinoma of the larynx and

from cylindrical carcinoma of the rectum. All these were spoken of as cases of multiple carcinoma, and it was believed they had no direct relation to one another, in the sense that no one of them depended for its occurrence on any other of them. Next, carcinoma might occur in parts of the body in direct relation with one another through the medium of the lymph or blood. Thus, the breast was the seat of carcinoma, and the axillary glands become affected. Or, carcinoma attacked the rectum, and growths of carcinoma were discovered in the liver. In these cases the carcinoma of the glands or liver was of the same variety as the carcinoma of the breast or rectum, and the theory was universally accepted that the one disease depended for its existence on the other, and that some part of the carcinoma, or something derived from the carcinoma, was conveyed from the breast into the glands through the medium of the lymph, or from the rectum into the liver through the medium of the blood. Such transference of the carcinoma was spoken of as a metastasis. Again, carcinoma was conveyed experimentally from one part of the same body to another, or from one animal to another of the same species. It was sometimes said that every successful implantation was neither more nor less than a metastasis; and this, to a certain extent, was true, but only within limits, for the conditions which surrounded the material which was implanted differed in some important respects from those which occurred in metastasis. Nevertheless, so frequent and successful was natural metastasis, that it might reasonably be expected that carcinoma would be most easily and readily conveyed from one animal to another by introducing some of the carcinomatous material into the blood, which presumably would convey it to various organs of the body, in one or other of which it would be likely to find a suitable soil and nourishment for its maintenance and development. Experiment had, however, taught us that this method was very unsuccessful, and it had almost ceased to be employed by those who experimented with cancer.

The accumulation of knowledge of the last few years enabled us to formulate, much more definitely than we could before, the conditions under which carcinoma was likely or unlikely to be accidentally communicated from one human being to another. Thus it would be at once apparent that all cases of reputed contagion of cancer in which the disease was not of the same variety must be unhesitatingly rejected; that cases must not be accepted where there was no evidence that the affected parts of the two individuals were from time to time in contact; that it was extremely improbable that contagion should take place from a covered cancer—such, for instance, as a cancer buried in the breast; or that the disease could be implanted in a part the covering of which had not been broken. These exclusions largely limited the number of possible cases of contagion, and the limitation was still greater when it was taken into account that sepsis of the tumor or of the broken part which came in contact with it was an almost absolute obstacle to the success of accidental implantation. For it was notorious that cancers which were exposed for the most part rapidly became septic, and ulcerated and suppurated. Indeed, the conditions which generally prevail were so unfavorable to accidental implantation in human beings that the event might be regarded as wellnigh impossible and scarcely worth the trouble of investigation, were it not for the occasional occurrence of what appeared to be examples of successful implantation in different parts of the body of the same individual. Such cases had long been known under the name of autoinoculation, and it was these, the speaker said, which would be studied in his address, for the key to the problem of the communicability of cancer in human beings surely lay in the study of autoinoculation. If autoinoculation could be proved on such evidence as would be admitted in a court of law, there was a *prima facie* case for contagion. And, if the proof of autoinoculation fell through from lack of sufficient evidence, whether in quality or quantity, it was no longer worth while to pursue the study of contagion from individual to individual. There were two locations in which autoinoculation would be likely to occur, if it occurred at all, and these were the vulva and the vocal cords, and accordingly Mr. Butlin had issued a circular letter to a large number of specialists or persons interested in gynecology, begging of them cases of contact-cancer of the vulva, and a similar letter was sent to those persons who were interested in laryngology. To these letters quite a number of replies were received, and from them he collected eight cases in which the evidence of autoinoculation was satisfactory. He also cited a case of contact epithelioma of the lips reported to the Boston Medical Society by von Bergmann in 1887. Several other cases were also referred to of apparent autoinoculation of cancer in other parts. The cases, he said, were not so numerous, but that he would fain have more of them; nevertheless, he thought they were too many and too constant in the circumstances of their occurrence to be explained on the theory of coincidence, and he believed they afforded conclusive evidence of the possibility of autoinoculation. He confessed, however, that his belief that carcinoma was a parasitic disease, and that the carcinoma cell was the parasite, predisposed him to think that the disease was capable of autoinoculation.

The study of autoinoculation was, however, only preparatory to that of the communicability of cancer from one human being to another, and he had set himself the task of investigating this question. Coition seemed to him the most likely of all conditions to place either the male or the female in danger of contracting cancer, yet from the nature of the case such occurrences must be rare, since the occurrence of open cancer in the case of the male would render him disinclined to coition, and in the case of the female an ulcerated cancer was generally septic, and so not likely to be communicable. Far, then, from wondering at the rarity of the reports of coition-cancer, he would be surprised if they were more frequent, and the small number of such cases must be compensated by the quality of those which were discovered.

The close of the week was, as usual, marked with numerous entertainments, excursions, etc., and the whole time the inhabitants of the city displayed the well-known Devonian hospitality.

SECTION OF MEDICINE.

Wednesday, July 31.—First Day.

WILLIAM GORDON, M.D., OF EXETER, IN THE CHAIR.

Indications for Operation in Cases of Intracranial Tumor.—Dr. J. S. RISIEN RUSSELL, in opening this discussion, prefaced his remarks with a plea for the early diagnosis of cerebral tumor and for early operation in suitable cases. In discussing the influence of diagnosis, he said that among affections that might be mistaken for cerebral tumor were hysteria (especially in tumor of the frontal lobe, general paralysis, disseminated sclerosis (especially in tumors of the cerebellum and mesencephalon), cerebral thrombosis (especially from those cases of tumor in which the symptoms came on rapidly), and cases of thrombosis with headache and vomiting and other severe initial symptoms. As to the conditions under which operation might be recommended: When there was reasonable certainty of the diagnosis of cerebral tumor a decision had to be arrived at whether the object in view was to effect cure or merely to relieve symptoms and prolong life. Before recommending an operation to effect cure, the first step was an accurate localization of the position of the tumor. Localization might, however, be not absolutely accurate and yet be near enough to allow of valuable results being obtained by operation. Cases were referred to in which, though localization was apparently obvious, no tumor was found at the operation, and in which much relief in regard to the symptoms followed the opera-

tion. But even if the localization were quite accurate, the position of the tumor had an important bearing on the question of operation, which might be negatived if deep in the hemisphere, if far forward in the middle cerebellum, or if lodged in the mesencephalon; in there, no cure could be hoped for. The nature of the growth also was of great moment. Guidance might be obtained from the length of the history, but it was to be remembered that tumors in the silent regions of the brain might last for a long time without giving any indication of their existence. Slow progress in a non-silent region, however, was somewhat in favor of its simple nature. The more diffuse the tumor the less likelihood was there of cure; similarly, operation was contraindicated if the tumors were multiple, especially if metastatic. Cases of simple nature were more common in the cerebellum and lateral recesses than in the hemsipheres. In regard to syphilitic tumors, some were of so chronic character as to be apparently incapable of benefit by giving mercury and potassium iodide; unless marked improvement followed in a few weeks from medicinal treatment, operation should be had recourse to. The probable effects of the operation had to be taken into account—as paralysis and risk to life from shock, hemorrhage, sepsis, etc. The rule of operating in two stages tended in some cases to obviate these risks, although death had been known to occur from failure of respiration in the interval between the two operations. No definite rule should be laid down on this point. It was to be looked for that a certain degree of paralysis would follow removal of tumor of the brain; such should be accepted, but whether a permanent aphasia should also be was a question for the patient to decide. As to recommending the operation merely with the view to relieve symptoms and prolong life, the former object was attained by opening the skull alone. It had, however, been thought that removal of part of the tumor retarded its growth and so prolonged life. No patient should be allowed to become blind from discarding operation. Lumbar puncture as a temporary measure was, as such, of value in relieving symptoms until a set operation could be undertaken.

Sir William MacEwen thought operation should sometimes be done in the absence of the classical symptoms of cerebral tumor. He agreed, moreover, that in some cases of syphilitic tumor operation was urgently required, especially if the tumor was large or there was caseation. What might be a sufficient trial of drugs was ordinarily left to the physician, but it should not be, he thought, many months. As to doing the operation in one or two stages, it was a good plan to decide after the first stage was done whether the further operation should be proceeded with or be postponed, according to the condition of the patient in regard to shock at the time. Relief of distressing symptoms was strongly to be desired, and operation recommended accordingly, and he had often seen the paralysis resulting from operation entirely clear up. In cases where aphasia or sphincter paralysis seemed inevitable, he would hesitate to recommend operation. In regard to lumbar puncture, there were not sufficient data to show its degree of efficacy or otherwise.

Dr. Mitchell Clarke referred to the cases of apparent tumor in which no tumor was found—cases of so-called "pseudo-tumor," in some of which blindness occurred. Some of these cases were doubtless, as Oppenheim had suggested, cases of internal hydrocephalus with serous meningitis. The difficulty of distinguishing between direct and indirect symptoms (as from edema) was alluded to, also the recent improvement in the prospects of patients suffering from tumor of the cerebellum, especially of the lateral lobes, to cases of cerebellar tumor commencing with auditory symptoms; to the value of tenderness of the scalp in localization; to the method of percussing the skull. If in syphilitic cases there was no definite improvement in three or four weeks, he thought there was no reason to persist in medicinal treatment. If the blood pressure were well maintained, the operation might be done at once and not in two stages.

Mr. Marcus Gunn said that in regard to so-called optic neuritis in its early stages evidence of inflammation was wanting, and the ophthalmoscopic changes were due, he believed, not to inflammation, but to the pressure of edema. The occurrence of these signs in greater frequency among hypermetropic patients was emphasized, and it was suggested that the shape of the globe of the eye had a mechanical influence on the production of these signs, the increased pressure within the optic sheath acting more on the nerve than in myopia with its wider sheath space. Certain stages of the papillitis were enumerated, including redness of the disk, swelling hemorrhages, impairment of vision, and late pallor. By a relief of intracranial tension, when the swelling was not of long standing, the prognosis as regards sight was good; if pallor had ensued, *i.e.* in the later stages, it was bad. Much swelling or the presence of hemorrhages were not absolute contraindications of recovery. Removal of the tumor did not seem to have any more beneficial effect than mere opening of the dura. Some of the best results as regards the eyes had followed removal of cerebellar tumors. His impression was that lumbar puncture would not give such relief of the papilla changes, as opening the skull; the cranial operation afforded more and more permanent relief.

Dr. Newton Pitt asked in what proportion of cases where intracranial tumor had been diagnosed was operation possible or advisable. Internal hydrocephalus following accident was discussed as confused with intracranial tumor. The question arose what good could be done in this condition when discovered by the operation; one case was mentioned in which drainage of the lateral ventricles had done much good, in most cases. This was not so. Cases of "pseudotumor" were mentioned, and the suggestion that they might be obsolescent tubercle made. At necropsies on cerebral gumma, he had always found a fibrous caseous mass left behind; he knew of no evidence of a gumma in the brain having entirely cleared up under drug treatment.

Mr. Donald Armour thought some ambiguity had arisen in regard to the term "operable" as applied to cerebral tumor; it had been applied by some as to be almost synonymous with curable. He would describe as operable any brain tumor which could be wholly or partly removed with improvement in the patient's symptoms. The chief cause of failure to obtain a cure was the infiltrating nature of the tumor. It was a question to be decided in each case whether removal of portion of the tumor was likely to benefit by arresting the growth or ameliorating the symptoms. Operation in every case should include exposing the tumor, and removal of the whole should be aimed at. Palliative operation might be undertaken for tumors which, though localizable, could not be removed, or even in non-localizable cases. Should exploration for subcortical growths be undertaken? The reply depended on whether any important function of the brain would be interfered with thereby.

Dr. W. Osler thought it a reasonable scepticism on the part of the profession in regard to the value of operation in cases of cerebral tumor, when general surgery, and not highly special surgery, was involved. He alluded to the remarkable interludes in the symptoms seen in certain cases of brain tumor. He was not sceptical of cure of cases of gumma in the brain by medicinal treatment if begun early. In the brain the coexisting arterial change had an influence on the result.

Dr. W. B. Lees said he believed that in some cases of

tumor of the lateral lobes of the cerebellum very great relief might be obtained by tapping the lateral ventricles, and referred to several instances, both of congenital hydrocephalus and of cases of posterior basic meningitis. He alluded to the occasional occurrence of prominence of the bone over intracranial tumors, particularly in cerebellar tumors and in children.

Dr. E. Bramwell thought that in every case of intracranial tumor coming to operation a definite plan should be determined upon between the physician and surgeon as to what should be done under certain circumstances, and particularly bearing on this question whether it was worth while to attempt to remove a subcortical tumor.

The President, Dr. William Gordon, described a case of tumor above the tentorium with unconsciousness, in which no relief was obtained from tapping of the lateral ventricles; trephining below the tentorium gave permanent relief; and another case with improvement after the second operation.

Dr. Risien Russell, in closing agreed that the absence of classical signs did not negative operation. As to drainage of the lateral ventricles, he thought it was not an operation for permanent relief any more than lumbar puncture, and was not to be compared with trephining. He had not himself seen any necropsy on a case of gumma healed by medicines with complete disappearance of the gumma. In decompression operation it was of the first importance to trephine over silent regions of the brain.

Cerebrospinal Meningitis.—Dr. A. G. Robb then read a paper based on observations on the recent outbreak of cerebrospinal meningitis in Belfast, including 230 cases. Three kinds of meningococcus (Kolle's, Wassermann's, and Ruppel's) serum were used in seventy-nine cases, with a mortality of 74 per cent. Lumbar puncture gave occasionally much relief. The opsonic method after the sixth day gave more reliable diagnostic indications than lumbar puncture and bacteriological examination of the cerebrospinal fluid. There was no evidence in any case of direct infection through contact.

Dr. William Osler congratulated the Belfast profession on the way they had combated the epidemic. It was a most mysterious epidemic disease, paralleled only by one other disease—pneumonia. In view of the alarm stirred up in regard to direct infection, the experience of the Belfast epidemic was of much value. He regretted the failure there of the serum treatment.

Dr. F. J. Poynton remarked on the increase in the number of cases in two London hospitals of posterior basic meningitis during last winter. Two or three remarkable recoveries followed serum treatment. He alluded to cases with arthritis.

Dr. McKisack alluded to the evidence bearing on the identity or otherwise of the epidemic and the sporadic posterior basic forms. In the present epidemic agglutination tests suggested that there were different strains at least of the microorganism, and some evidence pointing to the occurrence of different organisms.

Dr. Clive Riviere read a paper on the tuberculin treatment of tuberculosis in children.

Thursday, August 1—Second Day.

Diagnosis of Acute Pancreatitis. Dr. W. Osler, in opening the discussion, referred to the time when the pancreas was considered of little or no importance, to the time of the appearance of the work of Pitz, and to the later period dealing with the pancreatic ferments, and the relation of the pancreas to diabetes.

Of acute pancreatitis there were two groups—one with swelling of the gland, which might be due in part to coincident hemorrhage, and the other in which the gland was in a state of suppuration or necrosis. It was often difficult to say whether the hemorrhage had preceded or followed the inflammation. One important distinctive point anatomically was that in the acute pancreatic hemorrhage there was no fat necrosis. Of acute pancreatitis there were three chief causes: first, a mechanical one, as a stone in the common bile duct, leading to bacterial infection, but stone in the pancreatic duct was rare; secondly, chemical irritants as bile, duodenal contents, and gastric juice; thirdly, and most important, the various forms of pathogenic bacteria existing in the intestine. The pancreatic juice had bactericidal properties, and it was only when stasis occurred that infection resulted. The frequent association of gallstones with acute pancreatitis (in nearly half the cases) was remarkable; the stone situated in the ampulla of Vater was especially a cause. But a stone might exist for years in this position without causing suppuration, merely showing recurring chills, slight jaundice, pain, and fever from time to time. It was in these cases, however, with stasis of the pancreatic juice that acute pancreatitis was apt to occur. Bile alone could not probably cause the disease short of bacterial infection. A very large group of cases were those with gastrointestinal disturbance, many of whom were alcoholic, and possibly had duodenitis with catarrhal blocking of the duct. Of other less common causes were such as mumps, typhoid fever. From the point of view of diagnosis there were two types of cases, the acute and subacute. The acute was one of the severest forms of the "acute abdomen" with sudden prostrating agony referred to the abdomen, occurring in paroxysms, almost immediately followed by vomiting, like that of an acute obstruction of the upper part of the small intestine, intense shock, often a diffuse lividity, while tenderness might be present from the onset over the upper part of the abdomen, and a diffuse swelling might appear, which might, however, be obscured by the rapid distention of the abdomen. A diagnosis of acute pancreatitis was often quite impossible; all the symptoms might be found in severe hepatic colic or in acute perforation of the stomach. The history was of the greatest importance, as of alcoholism in the middle-aged, or with record of gallstones, and then the sudden symptoms. Death usually took place in three or four days from the onset. In the suppurative form the symptoms were less acute at first; there was less urgent pain, but fever occurred, and a tumor mass between the ensiform and the navel. The tumor might extend to the left reaching to the flank. The stools and urine were characteristic of pancreatic disease. The stools might contain fragments of necrotic pancreas or the typical excess of fat. As to prognosis of a large series, 90 per cent. of those not operated on died, and over 50 per cent. of those operated on were saved. Those due to gallstones were more especially fatal.

Dr. P. J. Cammidge referred to fifty recent cases, of which only five were diagnosed during life, showing the difficulty of the diagnosis. As helps, he recommended the examination of the excreta. In the majority of the cases of acute pancreatitis there was constipation. As to the urine, he had investigated seven cases of acute pancreatitis and one of subacute; the only striking feature was a considerable quantity of acetone and diacetic acid, many calcium oxalates, crystals, bile in the urine, and urobilin. It had been said that 10 per cent. of the cases had glycosuria, but none of these had this except one, when seen nearly a year after the attack. He referred to the pancreatic reaction in the urine he had devised, which was given by several of his cases.

Dr. W. Newton Pitt referred to the question of the mortality of the acute cases, describing a supposed case following a blow on the abdomen with epigastric swelling, which recovered; a second case, with a very septic mouth, suggesting a bacterial extension of the pancreatic duct, a swelling to the right of the epigastrium, and suppuration found on operation.

Dr. Craven Moore referred to four necropsies he had made on cases of acute pancreatitis. In three of the cases there was distinct history of alcoholism; in all there was history of anomalous dyspeptic attacks, called "bilious," the final attack coming on with sudden, severe pain, tenderness, pyrexia (101°), rapid pulse (100+), and extreme collapse with cyanosis of the extremities. His patients

looked far more ill than those suffering from perforative peritonitis. In one case the pain, at first general, became later most marked in the right iliac region simulating appendicitis. Two of the cases developed acute maniacal delirium with dilated pupils. The possibility of recovery from acute pancreatitis must be kept in mind. It was possible that the preceding attacks of causeless dyspepsia were really slight attacks of acute pancreatitis. Cases of gastric succorrhea might possibly belong to the same group.

Dr. F. J. Poynton referred to a case of ulcerative endocarditis, in which infarcts with acute inflammation were found in the pancreas, and to celiac disease in children with white stools and symptoms of severe abdominal disease and wasting.

Dr. H. Davy referred to a case of pancreatic disease with an acute onset, followed by the development of a large cyst in the abdomen, recovery following drainage.

Dr. Northrup remarked on the importance of directing attention to obscure diseases.

Dr. Tyson referred to two cases of embolism of the superior mesenteric artery, which had been diagnosed as acute pancreatitis, but which showed blood in the stools.

Dr. Morrison alluded to cases of epidemic chronic diarrhea with fatty stools, but without jaundice, and in some of these was found evidence of fibrosin of the pancreas and ulceration of the colon.

Dr. Nolan also alluded to and described a case of embolism of the superior mesenteric artery simulating acute pancreatitis.

Dr. Osler, in closing, said he had seen several instances in which all the symptoms of angina pectoris were abdominal. The great majority of the cases probably went on to a fatal termination unless operated on; the patients were really hardly in a condition to encourage operation. The picture was much more severe, as a rule, than in cases of acute perforative peritonitis. He did not think the picture of gastric succorrhea was at all like that of acute pancreatitis. Celiac disease quite possibly had an association with the pancreas. Bloody stools differentiated embolism of the superior mesenteric artery from acute pancreatitis.

Dr. W. P. Northrup of New York then read a paper on the treatment of pneumonia and other acute infectious diseases by open-air roof wards in metropolitan hospitals.

Dr. J. Michell Clarke of Bristol reported a case of lymphadenoma treated with *x*-rays.

Dr. Samuel West of London read a paper on pericarditis, including observations on symptomatology and treatment, recommending the administration of opium in many cases, and discussing the precautions for paracentesis.

Dr. W. Hunter of London read one on the effect of oral sepsis and antisepsis in scarlet fever bearing on such complications as angina and adenitis.

Dr. W. J. Tyson of Folkestone read one on the prevention of appendicitis.

Friday, August 2—Third Day.

Rheumatoid Arthritis and the Morbid Conditions Which Simulate It, with Special Reference to Pathology and Treatment.—Dr. A. P. Luff, in opening this discussion, said that although there were many forms of infective arthritis resembling rheumatoid arthritis, yet he believed it to be an entity—a constitutional disease due to bacterial invasion. The toxins produced by the organisms gave the nervous changes, pigmentation, etc. It might be distinguished from subacute rheumatism by not reacting to salicylates. It always began in one joint, but shortly it became polyarticular. The "monarticular forms" he thought were traumatic and should be called osteoarthritis. Rheumatoid arthritis occurred in two forms, acute and chronic, according to the degree of virulence of the infection. Comparatively slight injuries might lead to the commencement of the manifestation of the disease. In the acute form the synovial membranes were mainly affected. In the chronic, the cartilages and bones. The cases with Heberden's nodes, the mildest type, were more common in women than in men. In the majority of cases it was a final disease, but in some cases a previous arthritis of other forms might predispose, as might any debilitating condition. Uric acid had nothing to do with the disease. As to treatment, to be successful, it should be commenced early and persevered with for a year or two. Everything must be done possible to keep the patient's health at a high level. If taken early it was curable; if late it might be relieved, but not more than that. It required good and nutritious feeding, unlike gout; animal food should be taken freely. The drugs he had found most useful were guaiacol and potassium iodide. The guaiacol probably acted by inhibiting the organisms in the alimentary tract, and possibly by combining with the toxins. The iodide probably acted as an absorbent. The best way of giving guaiacol was as the carbonate in cachets increased from 5 to 15, or 20, grains three times a day. It was capable of arresting the disease in a large number of cases. In late cases mobility of the joints might be promoted by superheated air, massage, passive movements; brine baths, and douche massage. As to climate, dry heat improved the condition, and damp cold increased it. Egypt was one of the best winter resorts.

Dr. Strangeways said he believed there was no such disease as rheumatoid arthritis. At Cambridge they had studied the cases of arthritis (groups usually termed rheumatoid arthritis) from the literature, mostly valueless, from clinical notes (which were too much based on the clinical entity theory) on the lines of geographical distribution; family history, sex, age at onset, etc., from the morbid anatomy and histology, bacteriology, metabolism (the excretion of urates was altered) and from *x*-ray changes—some cases showing no joint changes, others atrophic (infective), and others hypertrophic, the last allied to gout, and all probably infective diseases.

Dr. Henry Davy thought little or nothing was known about the disease. Rheumatoid arthritis, so-called, was rare in the Exeter district of Devonshire. He had never seen a case cured. He believed that rheumatoid arthritis included a mass of very different kinds of arthritis, including even cases of tuberculosis of the joints.

Professor T. McCrae argued that the disease had a definite character, but many different types. He believed it to be an infectious process, and resembling in some respects the arthritis of gonorrhea or typhoid, though clinically different. He had never seen a case of rheumatic fever pass on to rheumatoid arthritis. If, in cases of the polyarticular forms of rheumatic fever, any permanent changes were left in the joints, it was necessary to revise the diagnosis. The *x*-rays were most useful in regard to diagnosis and for ascertaining how much damage was present in the joints. The treatment should be very much on the lines of that of tuberculosis—hygienic and dietetic. He believed in palliative treatment by Bier's hyperemic methods. Morbid anatomy was of little value in the study of the disease; much more was to be learned from operation. Apparently, monarticular forms on examination proved to be really polyarticular. Patients were often left with but little damage. He believed that in most cases the changes began in the cartilages, but not advancing far in some.

Dr. W. R. Gore believed the original cause of the disease was an infection from the gastrointestinal tract. The chief differential diagnosis was between early gout and rheumatoid arthritis. Treatment must be systematic and prolonged; the digestion should be put in order, easily fermentable food avoided, and proteid and fat freely given. He believed in Spa treatment for the condition, endeavoring especially to combat the intestinal fermentation. Electric light baths and massage were the best forms of local treatment; he also had found the hyperemic treatment of Bier good.

Dr. W. J. Middleton drew attention to the importance of considering the previous health history of patients. He believed the disease to be due to many different organisms, and thought its immediate cause was toxemia. He ap-

proved of the sanatorium principle in the treatment of the disease. He believed in counterirritation to the spine, Dr. Latham's method for the condition.

Dr. W. J. Tyson argued for the prevention of rheumatoid arthritis by daily exercise of the joints with good ventilation and dryness of dwelling houses.

Dr. Preston King really doubted whether there was such a disease as rheumatoid arthritis. He thought many cases were allied to gout, and that gonorrheal rheumatism was clinically indistinguishable from it sometimes.

Dr. J. O. Symes thought that two distinct diseases were included under the name of rheumatoid arthritis—one with fibrous structures affected, and the other the bones, and he believed that the two did not pass into each other. Some cases were due to bacterial infection and some due to altered metabolism in both groups. As to the bacteriology, he had found various cocci, but never anything specific. He believed it might arise from the gonococcus and many other organisms. The chief distinction to be made was between subacute rheumatism and commencing rheumatoid arthritis. Among other distinctive points was that the fluid from a subacute rheumatism joint showed an excess of polymorphonuclear leucocytes, but not that in rheumatoid arthritis, which showed a mononuclear count.

Dr. Michael Foster believed climatic treatment was useful for the relief of pain, but it was impossible to say which climate would effect this. For improvement of nutrition, probably the warmer place within limits the better, sunshine favoring an open-air life. The essentials of treatment were, he believed, identical with those of the open-air treatment of tuberculosis, with the exception that he would give stout. Except for the relief of pain, he believed drugs useless. Passive movements and electric baths were of great value.

Dr. W. B. Lees considered that the group called rheumatoid arthritis were in urgent need of analysis; excluding gout, rheumatism, syphilis, tubercle gonorrheal, and tabetic cases, the rest were called rheumatoid arthritis, but in this group there were probably at least three or four diseases. First, among these were the cases described by Dr. Still, an insidious polyarthritis occurring in children and associated with enlargement of the spleen and lymph glands—that must be a microbic disease. Secondly, there were the acute or subacute cases occurring in young women. Some of these at least were distinguishable from rheumatism, but others were probably truly rheumatic, and should be treated energetically as rheumatism with sodium salicylate. Thirdly, cases in middle-aged women with much bony deformity, also probably microbic and possibly associated with an insufficient consumption of fluid.

Dr. F. J. Poynton had investigated with Dr. Paine a case of rheumatoid arthritis, and had isolated a micrococcus with which they had produced a rheumatoid arthritis in rabbits—a periarthritis and an osteoarthritis—but the same organism might produce a monarthritis or a synovitis. Many cases of rheumatoid arthritis of the joints were, he believed, essentially rheumatic, comparable in their pathology with malignant endocarditis as affecting the heart valves. He believed, too, that there was much in the rheumatic gout idea, the soil provided by a gouty inheritance aiding the infection.

Dr. Sykes also thought there probably was a gouty factor. In some of the cases there might be a bacterial factor from the beginning, but in the majority he believed that came in later. He approved of the system of collective investigation. Physical treatment—exercise, electricity, and heat—was the chief thing

Dr. Fox had found rheumatoid arthritis very prevalent in the Plymouth district of Exeter. Drugs, he thought, were useless; heat, electricity, and physical exercises were the mainstay.

Dr Draper thought that ground air was an important cause

Mr Greenver advocated surgical treatment of the joints in some cases of rheumatoid arthritis—washing out the joints.

Dr. Odell had found guaiacol and hypophosphites, and ichthyol of especial use.

Dr. T. Morrell Thomas had found the breaking down of adhesions useful.

Dr. W. Gordon thought our knowledge of the subject was chaos which was shaping itself. He had found guaiacol carbonate of much value.

Dr. Luff, in reply, emphasized the necessity of early diagnosis. The simple method of distinguishing it from rheumatism was that it did not react to salicylates. Its prevalence in Plymouth he ascribed to the moist seaside climate. He had not found it possible to use the Bier method when many joints were involved. He had not found counterirritation to the spine of any value in rheumatoid arthritis. He could not agree that it was a rheumatic disease; he believed the microorganisms would be found to be different.

(*To be continued.*)

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Twenty-fourth Annual Meeting, Held at Washington, D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

(Special Report to the Medical Record.)

The President, Dr. Thomas Darlington of New York, in the Chair.

(*Continued from Vol. 71, page 840.*)

The Effect of Florida Climate Upon Acute and Chronic Disease.—Dr. Frank Fremont-Smith of Washington read this paper, pointing out the advantages of the climate of Florida, from which it was manifest that there was little fear of serious acute illness by winter residents of that State. The improving effects of the climate upon chronic diseases was said to be greater than that of sea-level summer in the north by reason of almost continuous sunshine, absence of evening chill, and the slighter diurnal temperature variations. Diseases of the circulatory and excretory systems were said to find their specially favorable conditions, particularly those forms dependent upon arteriosclerosis, local or general. He had seen cases of albuminuria greatly benefited by prolonged residence. Gouty and rheumatic subjects with incipient neuralgias or neurites had improved. Acute stages of pulmonary tuberculosis did not receive the same advantage as in the more invigorating climates. The advantages of easy accessibility, freedom from acute and climatic illness, and the toning down of overworked nerves, associated with its tendency to simulate Nature's restorative processes were claimed for Florida's influence upon health and disease.

The Blood Pressure as a Guide in the Treatment of Hemoptysis.—Dr. Edward O. Otis of Boston said that in the treatment of no symptom or complication of disease did the old aphorism of Hippocrates, "Experience is fallacious and judgment difficult," seem so true as in that of hemoptysis. Eighteen cases, mostly recurrent, had been observed in which the blood tension was taken at or as soon as possible after the hemorrhage began. The author suggested a plan of treatment somewhat as follows, provided, that any active treatment was indicated: First, a knowledge of the blood pressure of the patient from previous observations. On the occurrence of the hemorrhage, ice, morphine, and atropine subcutaneously, and, depending upon the amount and rapidity of the hemorrhage, the inhalation of nitrite of amyl. A laxative dose of sulphate of magnesia, and, if the bleeding persisted or was recurrent, nitrite of sodium or nitroglycerin if blood pressure was high for the individual, or if low, ergot or ergotin subcutaneously. The suggestion

of ergot, although a heretical doctrine, had apparently proved itself of value in at least a few cases when other remedies had failed.

Dr. Delancey Rochester was convinced of the very slight effect upon blood pressure of any drug, nitroglycerin being the only one having influence in lowering the pressure, and this only temporarily.

Dr. Samuel A. Fisk suggested the beneficial effect of fresh air in coagulating the blood and of calomel in diminishing blood pressure.

Dr. Thomas A. Claytor of Washington agreed with Dr. Rochester in his observation of the temporary effect of nitroglycerin in reducing blood pressure. Rest, diet, and purgation had been about the only satisfactory methods in his experience.

Dr. Frank Fremont-Smith observed that the value of the nitrites seemed to lie principally in relieving the spasm of the blood-vessels in which high tension exists.

Dr. R. H. Babcock of Chicago was surprised at the moderately high blood pressure—126 according to the Janeway instrument—in tuberculous conditions. His experience also showed that the nitrites had little influence. In hemoptysis with high blood pressure, in addition to rest he would use remedies to quiet the heart's action. With low blood pressure he would question the advisability of giving ergot, believing that abdominal pressure or ligation of the extremities would be more efficacious.

Dr. Charles Denison advocated immobilizing the part of the chest from which the hemorrhage started.

Dr. Judson Daland agreed with Dr. Babcock in the importance of quieting the heart's action. He believed that ergot had not yet established itself as a remedy of value in the treatment of hemoptysis. His opinion had been somewhat influenced from observation of hematuria in acute Bright's disease in which the hematuria ceased upon the withdrawal of the ergot.

Dr. F. M. Pottenger's experience was that hemoptysis was not so severe in sanatoria is in outside practice. He rarely did more than to quiet the patients by reassuring them mentally. When necessary to use morphia he gave it only in small doses. For lowering the blood pressure he employed nitroglycerin and veratrum viride, giving the veratrum viride at about the time the blood pressure was again rising.

Dr. Thomas Darlington spoke of analyses made by the Department of Health of New York of nitroglycerin tablets. The small percentages of nitroglycerin found made the tablets practically useless. Another point in connection with nitroglycerin, personally investigated some years ago, was that any form of ammonia overcomes the effect of nitroglycerin. Reference was made to the fact of the occasional combined use of these drugs which are directly incompatible.

Dr. Otis, in closing, said that the main object of his paper was to bring out any observations which would aid in definite and precise treatment of hemoptysis and blood pressure and expressed the hope that any observations made in sanatoriums and private practice would be published.

Wednesday, May 8—Second Day.

The Relative Value of High and Low Altitude in the Treatment of Tuberculosis.—Dr. F. M. Pottenger of Monrovia, Cal., concluded from his observations upon this subject that high altitude is not an essential in the treatment of tuberculosis and that the great majority of cases can be treated to best advantage at low elevations. The first point to be considered in choosing a climate for a tuberculous patient was said to be his ability to respond to the demand for tissue change which will be made by such climatic change. This point must be determined upon regardless of the question as to the adaptability of high altitude to the treatment of tuberculosis. High altitude was regarded as contrary to the principles of rest in inflammation in general and in tuberculosis in particular in causing greater activity on the part of the lungs and throwing great strain upon the already overtaxed heart. Another point considered was the apparent unreasonableness of placing an individual deprived of a portion of his aerating surface under conditions subjecting him to a demand for increased respiratory effort and subjecting the heart to more strain. An explanation of the necessity of patients in whom the disease had been arrested in high altitudes remaining there would seem to be explained by the increased size of the heart and lungs attained in the adjustment to the high altitude, and that in the return to the low altitude these organs underwent readjustment, entailing a retrograde process.

Report on Two Hundred Charity Cases of Pulmonary Tuberculosis, under Sanatorium Treatment at Los Angeles (1903-1907).—Dr. W. Jarvis Barlow of Los Angeles in reporting these cases laid emphasis on the fact that patients in all stages were taken and that 92 per cent. were beyond the first stage. The purpose of the report was to show the possibilities in the treatment of advanced cases. The best working plan had been found to be not to take the poor absolutely free but to make a charge of $5, which is usually paid from charitable funds. The necessity of making the patients absolutely comfortable physically and mentally was mentioned. The outdoor treatment was described. No tents are used, but cottages, so arranged that the improved patients are practically in the open the whole of the twenty-four hours. From the 60 per cent. of the 200 cases treated, three were Californians; 82 per cent. of the total number had followed indoor occupations. The average gain in weight in all patients was seven pounds and the average loss 5.9 pounds. The weight on discharge was about 4½ pounds gain, because there were included the patients that died at the sanatorium. The best gain in three months of a far advanced case was 22¾ pounds. Of the total 200 cases, 46 1-5 per cent. of the second and third stages showed a marked improvement. Many of these again became wage earners. The great difficulty in the work of the sanatorium was found to lie in the fact that many of these patients must necessarily return to their wretched surroundings. Such patients kept under proper supervision could reach an arrested condition.

Subsequent Histories of One Hundred and Sixty "Arrested Cases" of Tuberculosis Treated at the Sharon Sanatorium, 1891-1906.—Dr. Vincent Y. Bowditch of Boston and Dr. Walter A. Griffin of Sharon, Mass., presented this paper, which was read by Dr. Bowditch. The histories of the patients discharged as cases of "arrested" pulmonary tuberculosis were given. The writers adhered to the conservative term "arrested" in speaking of cases in which the most important symptoms had disappeared before discharge, after a stay of varying periods of time in the sanatorium, many of these cases having justified by their subsequent histories the use of the less conservative term "apparently cured." Among the 362 patients discharged, 35 remained too short a time to accomplish definite results or were found to be nontuberculous and were not considered. of the 327 considered, 160 were classed as "arrested." Up to April, of these there were still living, 133; number doing well at last account, 6; number who relapsed and died, 21, many of whom were advanced cases. The diagnosis in the great majority of cases in later years was corroborated by the tuberculin test, when the sputa failed to show tubercle bacilli and the physical signs and history were not sufficient to give proof of tuberculous disease. Tuberculin was used therapeutically with caution in some cases which after a comparatively long period of hygienic treatment remained *in statu quo*. The results had been sufficiently impressive to the writers to warrant more extensive use of the remedy, although they still held a conservative position in regard to the efficacy of such treatment. They deprecated the indiscriminate or careless use of the substance. They emphasized the importance of sanatoria as educational centers and deplored the exaggerated statements of overzealous

people who claimed too much after favorable results were obtained. The belief was expressed that a certain number of patients received greater benefit by a radical change of climate when pecuniary conditions did not have to be considered, when the attitude of mind was favorable, and the case was not one of advanced disease.

Importance of Supervision of Patients After Leaving Sanatoria Apparently Cured of Tuberculosis.—Dr. Frederick I. Knight of Boston said that the satisfactory control of tuberculosis in the future would involve a continued knowledge on the part of some authority, not only of the individuals infected, but of their families and all surroundings. This duty should be assigned to special local boards composed of persons really interested in the subject who would work cautiously. One of the functions of such a board should be to supervise the patients returning from sanatoria apparently cured. The establishment of labor or farm colonies was regarded as one of the most promising ways of helping to maintain the health of those restored at sanatoria. Reference was made to the account by Woodcock of Leeds (Congrès Internationale de la Tuberculose, 1905) of his investigation of the possibilities of labor colonies. He reported that at Kelling in Norfolk, at Dr. Fanning's Sanatorium, which was practically a farm, all patients worked; even those unable to leave the shelters, carved wood and made mats, and their work was sold. An "after care" committee concerned itself with getting suitable situations for discharged patients. Dr. Fanning believed that idleness was the worst curse to the consumptives. Boucard, of Cannes, at the same Congress, had insisted that a part of the millions appropriated for the erection of sanatoria be used in establishing farm colonies.

Daily Care of Consumptives at a General Hospital as an Aid in Solving Local Tuberculosis Problems.—Dr. Arthur K. Stone of Boston gave a statement of the experiment of the House of the Good Samaritan in the care of ambulatory cases of tuberculosis. This care was shown to include daily medical supervision, out-door treatment, good food, and home supervision. The circumstances attendant upon the treatment was said to keep up the general morale of the patient. The patient's home was kept intact and the patient allowed to participate in the home duties night and morning. One disadvantage of the plan mentioned was the wear and tear of the patient incident to the coming and going to and from the hospital. Twenty-five patients thus cared for had added small addition to the administration force of the hospital. The cost per patient had been very small and the results good.

The Sleeping Canopy.—Dr. Charles Denison of Denver in presenting this paper described this canopy, which was designed to afford tent advantages indoors, and remarked upon the need of such means of ventilation. The author's design was exhibited and was illustrated by photographs and drawings suitable to enable anyone to construct or procure his own canopy according to his sleeping-room conditions. Dr. Denison thought there should be a rule of space per capita for sleeping purposes so advocated and enforced (by legal enactment if necessary) that no one could plead ignorance as an excuse for unappreciation of the relation of air space to health, such rule to carry with it the condition of renewal per hour. This necessity of sufficient air space, especially during the probably more susceptible sleeping hours, was regarded as the most vital consideration in connection with the tuberculosis crusade, not second in preventative importance to the quality of air in that space, nor to the infective germ of tuberculosis.

Personal Hygiene in the Prophylaxis and Treatment of Consumption.—Dr. Richard Cole Newton of Montclair, N. J., read this paper, remarking upon the relative prevalence of tuberculosis in the lower animals under varying conditions of habit and environment, and considered some of the predisposing causes of tuberculosis in man other than heredity. Conclusions were drawn from the foregoing as to the method of life best calculated to prevent the occurrence of consumption in man. Tuberculosis was shown to be a disease following maladaptation to the environment, improper habits, and defiance of nature's laws, and the assertion was made that nothing would stop its ravages entirely except a life controlled by the physical conscience and the prevention of the contraction a-- the disease. Were dairy cattle given more exercise, and never confined in stables, the author believed normal metabolism would be promoted, and that they would probably not suffer from consumption. In the same way, should negroes and Indians return to their life to which centuries of evolution had fitted them, the disease would probably disappear from among them in a generation. Infection was said to play a secondary part in the production of consumption, as did also heredity, the principal cause being a man's life, habits, and environment.

Dr. Roland G. Curtin believed that home-sickness would nullify the effect of the best climatic treatment possible. He believed also that it was possible to keep a person at home too long.

Dr. Charles L. Minor agreed that the care after return from sanatoria of patients filling positions with moderate salaries was a difficult question. Unless they could work in well-ventilated offices, have adequate provision for nourishing lunches and be much in the open air, the return to their occupations meant relapse to their former condition.

Dr. James M. Anders favored Dr. Barlow's efforts in the treatment of advanced cases, and thought that too often active measures were here abandoned. He felt that the profession failed in its plain duty when it failed to keep in touch with patients after their return from sanatoria. With a return to home environment resistance was lowered and the patient made especially susceptible to intercurrent attacks of bronchitis and influenza. The latter, if not properly handled, led to a relapse of the original disease. The same was true of cases apparently cured of pleuroeffusion. He thought it a reproach to the medical profession that so many of these cases developed into tuberculosis.

Dr. Delancey Rochester protested against the position he understood to be taken by Dr. Bowditch that the discovery of the tubercle bacilli is absolutely necessary to the diagnosis of tuberculosis. In place of the cloth and rubber bags with the paper napkins mentioned by Dr. Stone as supplied to the patients, he suggested the employment of paper bags which could be purchased for a few cents and destroyed. In the matter of proper nourishment for those returning to occupations from sanatoria he advises his patients to have milk delivered at the office, or take it from home, having two or three raw eggs mixed with it.

Dr. Otis agreed with Dr. Wright concerning the very great importance of properly caring for patients returned from sanatoria, and knew of no better way in which this could be done than by means of the farm colony. This should be attached to the sanatorium, and the patients there trained to work that they might be physically able to resume their occupations, or to take up outdoor work in country places.

Dr. Thomas W. Harvey regarded the question of sex of great importance in advising a patient whether he should be treated at home or in a sanatorium. In his experience women can be taken care of better at home than men. The fact that the man is the wage earner is an important factor in this. Men, however, do not bear well the discipline of sanatoria.

Dr. Leonard Weber thought the tendency was to look only at the patient in considering tuberculosis, while attention should be directed to the men who contribute to the development of the disease in employing child labor, running sweat shops and maintaining unsanitary tenement houses.

Dr. Pottenger joined with Dr. Barlow in his plea for active efforts in the advanced cases, believing they were not all hopeless. In addition to the improvement that could be made in the advanced cases an additional advantage

in their treatment in sanatoria lay in their removal as sources of infection and their return after treatment to educate those in their community in methods of prevention.

Dr. Bowditch, answering Dr. Rochester relative to diagnosis by the tubercle bacilli, said he did not regard the discovery of the bacilli necessary for an absolute diagnosis, but that in cases of patients not readily convinced this evidence was conclusive.

Dr. Denison had found the tuberculin test satisfactory in diagnosis. He referred to the statistics made in Glasgow showing the relation of the mortality in tuberculosis to poverty, estimated upon the ratio of one to three persons occupying a room. The mortality was shown to be twice as high in instances of three persons occupying one room as in cases where there was but one. He thought this favored the argument of his own paper that a certain air space per capita should be provided.

Some Notes on Aix-les-Bains.—Dr John W. Brannan of New York City gave some personal impressions of Aix. The water was said to be chiefly remarkable for its constant high temperature, 44° C., and its abundance, averaging over six million liters a day, delivered under very high pressure. The various ways of its employment were enumerated. The method which gives to it its reputation is the douche combined with the massage, and a detailed description of this was given from the author's personal experience. The chief contraindications to the treatment were said to be organic disease of the kidneys or liver and valvular disease of the heart with imperfect compensation.

Hemoptysis Due to Tuberculosis.—Dr. J. M. Anders of Philadelphia subdivided the cases into those occasioned by (a) congestion of the bronchial mucosa and lung-texture, and (b) ulceration or erosion of vessels, or rutpure of miliary aneurysms. The two classes were fully considered. The subject was further discussed under exciting factors; incidence, age, and sex; seasonal influence; clinical peculiarities, and a résumé given of treatment. Certain well-founded principles were said to be but dimly recognized by the present generation of physicians; for example, the bleeding from a hyperemic lung-texture afforded decided relief to the local pathological condition with symptomatic improvement as a secondary result. The therapeutic value of absolute rest in this condition and of restricted feeding, with light, unwarmed articles of diet seemed to be imperfectly grasped. The employment of prophylactic measures was inexcusably neglected. Dr. Anders' best results during the early active stage of hemoptysis have been obtained from the strict enforcement of absolute recumbency and quiet, and an arrest of the cough by codeine in mild forms and morphine hypodermatically in the severer cases. Unless there be obvious danger of inundation of the uninvolved lung-tissue, as in cases of profuse hemorrhage, the cough should be so arrested. Excepting the small class of cases in which opium is contraindicated, morphine, or opium in some form, rightly administered, was emphasized as the most serviceable single remedy available, its signal virtue being ascribable to the remarkable enhancement of a coagulum at the seat of bleeding.

Paroxysmal Tachycardia.—Dr. Philip Marvel of Atlantic City, N. J., in this paper said that the slight physical disability incidental to paroxysmal tachycardia, and the promptness with which the slight disturbed functional forces were again restored, following the arrest of the attack, should the attack be of short duration, contrasted with the marked disability often observed in tachycardia associated with myocardial disease, present two interesting features, and to some degree symptomatically characterize the two types. In the paper presented there were collated some of the recent views advanced as the probable cause of the disturbance and the probable reason pointed out for the absence of great systemic involvement in the former

Two cases were reported and reference made to cases reported in the literature. To the fact that the cardiovascular balance, early in the attack, in spite of the very rapid heart action, is so slightly disturbed, is attributed the absence of marked physical inability. The treatment, so far as the author knew, was said to be purely symptomatic.

Surgical Suggestions.

Epididymitis.—Crouse recommends the following dressing for the ambulatory treatment of this affection: Clip the hairs, lay the patient down, elevate the scrotum to deplete the parts as much as possible, then cut a pad of absorbent wool so that it will amply cover the parts reaching from the perineum and projecting up over the cord. Place a piece of wool, smoothly cut, between the penis and the abdomen, or permit the cord strip to be so cut as to approximate there, taking care that the part for the penis protrusion is not made too large. With these essentials one is ready for the application of the guaiacol, which should be applied to the extent of fifteen to twenty-five minims. Then quickly cover the entire scrotum, dipping the perineal portion of the absorbent wool well under the scrotum; hand the cord ends to the patient, who will thus support the organ while you cover the wool with oiled silk or gutta percha, which is cut to the same pattern as the wool. Work the suspensory from the perineal region forward over the entire mass, but while doing so avoid wrinkling the scrotal covering; slip the penis through the opening in the suspensory, pass the waistband about the body, buckle back straps, and then draw the waist-band as snugly as possible, elevating the entire scrotal mass as far up against and onto the pubis as possible.—*Indiana Medical Journal.*

Vomiting in Infants.—H. Ashley says that vomiting may be the expression of an irritant or toxin acting upon some distant part, as well as one acting locally on the stomach. In infancy the vomiting reflex is always sensitive, like the crying reflex, the coughing reflex, and the heat reflex. With children of a neurotic type, those who are sick and those who are badly nourished, this sensitiveness is exaggerated. Nearly all the troublesome cases are in those babies who are artificially fed. If there is stenosis of the pylorus vomiting cannot be prevented, while if the infant is breast-fed the mother's milk is, as a rule, too rich. In many of the cases there is gastric inertia, dilatation with gas from decomposing contents, and then rejection and intolerance. Washing out the stomach and then beginning again with small quantities of whey or diluted milk will often enable an infant to get a fresh start. Vomiting with fever may be the initial vomiting of scarlet fever, the severe and continuous vomiting early in pneumonia, the severe vomiting with high fever in influenza, persistent vomiting during diphtheria or convulsions, etc. Attacks of vomiting in neurotic children may begin suddenly and continue for several days, with drowsiness, with acetone in the breath and in the urine. These attacks are very suggestive of meningitis, but may be due entirely to gastrointestinal intoxication. Vomiting with peritonitis and obstruction of the bowels points necessarily to urgent conditions within the abdominal cavity.—*Pediatrics.*

Plaster-of-Paris Dressings.—Meisenbach says of the setting of plaster-of-Paris that chloride of sodium in small amounts hastens the set; in large amounts retards it; in any amounts it weakens the dressing by decreasing the crushing force and tensile strength. Dextrin in small amounts strengthens the dressing by increasing both the crushing force and tensile strength, but it also lengthens the time of set in direct proportion to its use. If the time of set is no object, it may be used to good advantage in certain cases, as for instance in making a plaster bed for multiple tuberculous bone lesions. Starch in small amounts (that which is contained in starch sized bandage) adds to the strength by increasing the tensile strength. It does not interfere with the set of the bandage. Portland cement when used in the plaster-of-Paris bandage has the great advantage over chloride of sodium and dextrin in that it can be mixed with the plaster before the bandages are made and that it materially strengthens the bandage in all of its essentials, *i.e.* increases the crushing force, tensile strength, and at the same time reduces the time of set and density. The density with it is less than the density of the pure plaster itself. The dressings made of the cement bandage are of a light sage color and are not as easily affected by perspiration. They are much stronger and lighter than the pure plaster dressings.—*American Journal of Orthopedic Surgery.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

DELAWARE STATE MEDICAL SOCIETY EXAMINING BOARD.

December 11, 12 and 13, 1906.

THERAPEUTICS.

1. What analogy exists between the nutrition of health, the disturbances of disease, and the action of remedies?
2. Give the origin of benzoin and menthol, with their therapeutical applications.
3. In uremic poisoning what remedies are required?
4. What is the physiological antagonism between belladonna and morphia?
5. What are the principal preparations used as antiperiodics?
6. Of what therapeutic value is amyl nitrate?
7. What respiratory stimulants exalt the functions of the respiratory center of the medulla?
8. For what is stramonium used, what are its physiological actions?
9. Give the preparations and doses of the mineral acids with their therapeutic effects.
10. Give the preparations of bismuth, how administered, and indications for use.

MATERIA MEDICA.

1. Give the preparations and classifications of phenacetin, somnal, and hydrogen dioxide.
2. What are the principal anthelmintics, mode of action?
3. Name twelve officinal alkaloids.
4. What are the officinal extracts, how obtained?
5. What is chrysarobin, where found and how applied?
6. Name the alkaloids of veratrum viride.
7. What are the preparations of guaiacum, give physiological action?
8. Name six motor excitants and six motor depressants.
9. Name the preparations of iron, their doses and incompatibles.
10. What is picrotoxin, what combinatory action does it represent?

CHEMISTRY.

1. What is analysis, and synthesis?
2. What is the difference between physical and chemical action?
3. What are the essential ingredients in air? Is it a mixture or a chemical compound? Give proof.
4. What are the chemical properties of phosphorus?
5. What is Labarraque's Solution, and upon what does its disinfectant value depend?
6. What are the physical and chemical properties of ammonia, and how does it differ from other alkalies?
7. Give method of disinfection in detail—1st, with sulphur; 2d, with formaldehyde.
8. Which is the more efficient, and why?
9. What are the best tests for albumin and sugar in urine?
10. What is eucalyptol, and what are its uses in medical practice?

HYGIENE.

1. Will the destruction of offensive odors remove the conditions injurious to health?
2. In what way may the application of fertilizers affect the public health, and how can it be avoided?
3. What are the nitrogenous constituents of food, from whence derived, and what are their functions?
4. What is the period and source of infection and the necessary time of quarantine, in (a) smallpox, (b) scarlet fever, (c) diphtheria, and what do you understand by quarantine?
5. How would you manage an outbreak of contagion among school children? Answer in detail.
6. Describe a practical method for the disinfection of clothing, bedding, etc.
7. How would you provide for an infant who never has the breast available? Name food you would prefer, quantity you would advise, and frequency of feeding, according to age.
8. What general preventive measures would you recommend to stay the increase of tuberculosis?
9. Give the advantages or disadvantages of a state sanatorium for the treatment of tuberculosis. How should it be constructed and managed?
10. What in detail is the duty of physicians in attendance upon infectious disease, to prevent its spread?

PATHOLOGY.

1. Give morbid anatomy of cerebral hemorrhage and name the common cause when it appears in early life.
2. How does the pathology of locomotor ataxia differ from that of ataxic paraplegia?
3. Define dementia and give its pathology.
4. State pathology of tinea circinata.
5. Define indicanuria, name its chief sources and the pathological conditions in which it is most usually found.
6. What is the pathological anatomy of pyelitis?
7. Name morbid anatomy of Hodgkins' disease.
8. Give pathology of biliary calculi.
9. State difference in pathology of catarrhal, ulcerative, and interstitial appendicitis.
10. How does tachycardia differ from bradycardia, and in what pathological conditions are they found respectively?

PHYSIOLOGY.

1. What is the function of the sudoriparous or sweat glands, where is the dominating sweat center located, and how is this excited to action?
2. Name the functions respectively of the anterior and the posterior roots of the spinal nerves.
3. Give functions of the liver and name the blood-vessels entering it.
4. In what way does the blood circulate through the heart?
5. What are the mechanical uses of saliva?
6. What gases have we in the stomach?
7. How do arteries differ from veins?
8. Are the movements of the lungs passive or active?
9. What changes are produced in the atmospheric air by respiration?
10. How does the function of an afferent or centripetal nerve differ from that of an efferent or centrifugal one?

SURGERY.

1. In ligating the superficial femoral artery at its lower third, what structures are severed and what are the anatomical relations?
2. Describe traumatic inflammation.
3. How and why are fever and delirium induced by physical injuries?
4. Bone fractures are how classified? Diagnose and treat a typical fracture of each variety.
5. Dislocations are how classified? Diagnose and treat a typical case of each variety.
6. Explain reasons for preferring any special operation for amputation of both forearm and leg.
7. Explain method of procedure in operating for relief of fistula in ano.
8. In operating for relief of urinary calculi, what method would you use and why?
9. Differentiate hydrocele and chronic orchitis.
10. Deep seated pus cavities are how treated?

ANATOMY.

1. The first vertebra is how attached to the skull?
2. Give shape, size, formation, and articulation of first and second vertebra.
3. Give shape, approximate size, origin, and insertion of trapezius muscles.
4. Describe choroid plexus and situation of 4th ventricle of the brain.
5. Give origin and distribution of superior maxillary nerve.
6. Explain origin and distribution of brachial artery.
7. Give branches of internal carotid artery and their distribution.
8. Give structure, situation, and size of gall-bladder.
9. Give structure, formation, situation, and size of the gastrohepatic omentum.
10. Give location, shape, size, structure, and blood supply of the diaphragm.

OBSTETRICS.

1. Name the internal female organs of generation and state the functions of each.
2. How would you diagnose pregnancy in the early months, before quickening?
3. Mention conditions that may require induction of premature labor. How would you produce the same?
4. What is ectopic gestation? Name its varieties and state how its diagnosis may be established.
5. How would you proceed if called to a case of neglected shoulder presentation?
6. Give causes, pathology, and treatment of ophthalmia neonatorum. What is the great danger?
7. State the causes and give the management of postpartum hemorrhage.
8. State causes and treatment of mammary abscess.
9. Name the important diameters and measurements of (a) the female pelvis, (b) the fetal head.
10. Give the positive and doubtful signs of pregnancy, beginning with those you consider of the most importance.

PRACTICE OF MEDICINE.

1. Mention the conditions that contraindicate general anesthesia.
2. Define arteriosclerosis. Give its etiology and state the age at which it is most liable to occur.
3. What are the symptoms and treatment of acute laryngitis in children?
4. Mention five possible complications of typhoid fever and your treatment of each.
5. Give symptoms and treatment of acute lobar pneumonia.
6. What is meant by immunity? In what ways may immunity be acquired?
7. Define neurasthenia. Give symptoms and treatment.
8. Differentiate tubercular arthritis from rheumatic arthritis.
9. State the symptoms and outline the treatment of (a) opium poisoning, (b) strychnine poisoning.
10. Give the symptoms and treatment of hydrophobia.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

DELAWARE STATE MEDICAL SOCIETY EXAMINING BOARD.

December 11, 12, and 13, 1906.

THERAPEUTICS.

2. *Benzoin* is a balsamic resin derived from the *Styrax Benzoin*. It is an antiseptic and disinfectant; it renders the urine acid; it is used in acute rheumatism, acute laryngitis, chronic bronchitis, and chronic cystitis.

Menthol is a stearopten derived from oil of peppermint. It is used in neuralgias and migraine, vomiting of pregnancy, gastralgia, and colic.

3. In *uremic poisoning* the first indication is to open up all the emunctories; measures must be taken to make the skin, kidneys, and bowels active; the hot pack, elaterin, pilocarpin are suitable agents. Then the respiratory and circulatory functions must be sustained; this can be done with strychnine and digitalis. If convulsions are present or impending, chloral or chloroform or bromides are indicated.

4. The physiological antagonism between *Belladonna* and *Morphia* is as follows: *Belladonna* (1) acts as an excitant and stimulant of the cerebrum; (2) produces dilatation of the pupil; (3) quickens the pulse; (4) first stimulates and then depresses the respiratory center; (5) decreases all the secretions, except urine.

Morphia (1) acts as a sedative on the cerebrum; (2) contracts the pupil; (3) slows the pulse; (4) does not at first depress respiration, but in overdose it paralyzes the respiratory center; (5) checks all the secretions except perspiration.

5. The principal *antiperiodics* are:—Cinchona bark and quinine, Warburg's tincture, arsenic, salicylic acid and the salicylates, eucalyptus, and iodine.

6. *Amyl nitrite* is used for the relief of angina pectoris, epilepsy, spasms, convulsions, whooping cough, asthma, laryngismus stridulus, strychnine poisoning, tetanus, and in threatened death from chloroform anesthesia.

7. Respiratory stimulants:—Strychnine, ammonia, digitalis, alcohol, ether, atropine, apomorphine, hydrocyanic acid, cold douche.

9. Mineral acids, with their preparations and doses:—Dilute sulphuric acid, 30 minims; aromatic sulphuric acid, 15 minims; dilute nitric acid, 30 minims; nitrohydrochloric acid, 3 minims; dilute nitrohydrochloric acid, 15 minims; dilute hydrochloric acid, 15 minims; dilute phosphoric acid, 30 minims; sulphurous acid, 30 minims; boric acid, 7 grains; (liquor antisepticus, 1 dram).

MATERIA MEDICA.

1. *Phenacetin* is an antipyretic and analgesic; there are no official preparations.

Somnal is a hypnotic; there are no official preparations.

Hydrogen dioxide is an antiseptic; preparation, aqua hydrogenii dioxidi.

2. *Anthelmintics* are agents which kill or expel worms inhabiting the intestinal tract.

Vermifuges (which expel the worms) are:—Scammony, jalap, and other purgatives.

Vermicides (which kill the worms) are:—Turpentine, male fern, kousso, pomegranate, santonine, quassia, tannin, spigelia, chenopodium.

3. *Twelve official alkaloids*:—Strychnine, atropine, quinine, morphine, codeine, cocaine, caffeine, physostigmine, hyoscine, hyoscyamine, pilocarpine, sparteine.

4. *Fluid extracts* are liquid alcoholic preparations of vegetable drugs in which one cubic centimeter represents the medicinal properties of one gramme of the crude drug. They are obtained by percolation and partial evaporation with menstrua of alcohol (either pure or diluted).

5. *Chrysarobin* is a neutral principle obtained from Goa powder, which is found in the wood of *Vouacoupoua Araroba* in Brazil. It is applied externally in an ointment.

6. The alkaloids of veratrum viride are:—Veratrine, veratroidine, jervine, pseudojervine.

7. The preparations of guaiacum are:—Tincture of guaiac and ammoniated tincture of guaiac.

Its action is:—diaphoretic, laxative, expectorant, and emmenagogue.

8. *Six motor excitants*:—Strychnine, digitalis, picrotoxin, pilocarpine, ergot, brucine.

Six motor depressants:—Alcohol, opium, aconite, chloral, belladonna, tobacco.

9. The preparations of iron, with their doses, are:—Reduced iron, 1 grain; ferrous sulphate, 3 grains; dried sulphate of iron, 2 grains; granulated ferrous sulphate, 3 grains; pills of ferrous carbonate, 2 pills; saccharated ferrous carbonate, 4 grains; syrup of ferrous iodide, 15 minims; pills of ferrous iodide, 2 pills; ferric chloride, 1 grain; solution of ferric chloride, 1½ minims; tincture of ferric chloride, 8 minims; Basham's mixture, 4 drams; solution of ferric subsulphate, 3 minims; ferric hydroxide with oxide of magnesium, 4 ounces; ferric ammonium sulphate, 7 grains; soluble ferric phosphate, 4 grains; tartarated iron, 4 grains; iron and ammonium citrate, 4 grains; iron and strychnine citrate, 2 grains; iron and ammonium tartrate, 4 grains; iron citrate, 4 grains; iron and quinine citrate, 4 grains; soluble iron and quinine citrate, 4 grains; pyrophosphate of iron, 4 grains; dialyzed iron, 10 to 30 minims.

Incompatibles:—Acids, acid salts, alkalies and their carbonates, and vegetable astringents.

10. Picrotoxin is a neutral principle found in the seeds of the *Anamirta paniculata*.

It represents the combined action of belladonna and nux vomica.

CHEMISTRY.

1. *Analysis* is the splitting up of a compound into its elements or into simpler compounds.

Synthesis is the building up of a compound from elements or from simpler compounds.

2. "A bar of soft iron may be made to emit light when heated, or sound when caused to vibrate, or magnetism when under the influence of an electric current. Under the influence of these *physicel forces* the iron suffers no change in composition, and, on cessation of the action of the inciting force, the iron returns to its original condition. But if the iron be heated in an atmosphere of oxygen, both the iron and a part of the oxygen disappear, and a new substance, a new chemical species, is produced, having properties of its own, different from those of either the iron or the oxygen. In this case there has been *chemical action*, causing change of composition, as the new substance contains both iron and oxygen. The result of such action is, moreover, permanent, and the new product continues to exist, until modified by some new manifestation of chemical action."—(Witthaus' *Manual of Chemistry*.)

3. The essential ingredients in air are:—Oxygen, nitrogen, carbon dioxide, water vapor, argon, and ammonia.

Air is a mixture, and not a chemical compound.

This is proved by the following facts:—(1) the composition is not always absolutely the same; (2) the proportion of the elements, oxygen and nitrogen, is not in any relation to their atomic weights; (3) when oxygen and nitrogen are brought together in the proper proportions, no chemical action occurs, and yet the resulting mixture has the properties of air.

4. *Chemical properties of phosphorus*:—Phosphorus has an atomic weight of 31 and a molecular weight of 124, there being four atoms to the molecule; it has a valence of three or five; it combines readily with oxygen, chlorine, bromine, and iodine; it is a good reducing agent; it is not acted on by hydrochloric or cold sulphuric acid, but is oxidized by nitric acid.

5. *Labarraque's solution*, or solution of chlorinated soda, is an aqueous solution of several chlorine compounds of sodium.

Its disinfectant value depends upon the presence of the chlorine which can be liberated.

6. *Ammonia. Physical properties*:—A colorless gas, with a pungent and irritating odor, and a caustic taste; it is very soluble in water and in alcohol.

Chemical properties:—It combines directly with acids to form ammonium salts.

It differs from the other alkaloids in being volatile, having a pungent irritating odor, being a gas, and in its action with acids.

9. Good tests for *albumin* in the urine are:—(1) the heat test, and (2) the nitric acid test.

Good tests for *sugar* in the urine are:—(1) Fehling's test, and (2) the fermentation test.

10. Eucalyptol is a neutral body obtained from oil of eucalyptus.

It is used for lotions and nasal applications, also in malaria, bronchitis, gonorrhea; on ulcers it has a disinfectant and stimulating action.

HYGIENE.

1. The destruction of offensive does not necessarily remove the conditions injurious to health.

3. The nitrogenous constituents of food are derived chiefly from the flesh of animals, fish, fowl, milk, eggs, and certain vegetable products (wheat, oatmeal, peas, beans, etc.). The constituents and functions are shown in the following table adapted from Notter and Firth's *Hygiene*:

Nitrogenous Substances	Examples	Functions
1. All substances containing nitrogen, of a composition identical with, or nearly that of albumin; proportion of N to C being nearly as 2 to 7.	*Animal:* Albumin, Fibrin, Syntonin, Myosin, Globulin, Casein, Albumoses, Peptones. *Vegetable:* Glutin, Legumin, Albumoses	Formation and repair of tissues and fluids of the body. Regulation of the absorption and utilization of oxygen. May also form fat and carbohydrate, and yield energy sometimes. In most foods the above, both animal and vegetable, are largely converted into albumoses and peptones during digestion.
2 Substances containing a larger proportion of N are apparently less nutritious; proportion of N to C about 2 to 5½.	Gelatin, Ossein, Chondrin, Keratin	These perform the above functions less perfectly, or only under particular circumstances.
3. Extractive matters, such as are contained in the juice of the flesh.	.....	These substances appear essentially as regulators of digestion and assimilation, especially with refereuce to the gelatin group.

7. For an infant seven weeks old the following will do:—Cream, half an ounce; milk, ten drams; milk sugar, half a dram; a pinch of salt, and ten drams of water. This quantity should be given every two hours, except at night (from 11 P.M to 5 A.M.).

PATHOLOGY.

2. In *locomotor ataxia* the degeneration of the posterior columns is most marked in the lumbar region; in *ataxic paraplegia* it is equally or more intense in the dorsal region. In *ataxic paraplegia* the lateral columns are also involved.

5. *Indicanuria* means the presence in the urine of an excess of indican. It is derived from the indol produced in intestinal putrefaction.

It is most usually found in gastric cancer, peritonitis, ileus, empyema, gangrene of the lungs.

6. The mucous membrane is congested and covered with mucus and desquamated epithelium. The inflammation (and pus) may extend into the substance of the kidney. When there is complete obstruction the calyces may be dilated, the kidney substance atrophied, and the entire kidney may become a sac of pus.

10. *Tachycardia* means increased frequency of the pulse. It is found in fevers, exophthalmic goiter, many forms of valvular disease of the heart, hemorrhage or tumor at the base of the brain, and after the ingestion of certain drugs.

Bradycardia means an abnormal slowness of the pulse. It is found in aortic stenosis, chronic myocarditis, during the puerperium, the convalescence from many fevers, hemorrhage or tumor of the brain causing increased intracranial pressure, myxedema, from certain poisons in the blood (as alcohol, tobacco, opium, and lead), and after the ingestion of certain drugs.

PHYSIOLOGY.

1. The function of the sudoriparous glands is the secretion of sweat. The location of the sweat center or centers has not been determined. There *may* be a dominating center in the medulla.

The center is excited to action (1) by direct action on the central nervous system, (2) by stimulation of certain afferent nerves, and (3) by changes in the composition or quantity of the blood.

2. The *anterior* roots of the spinal nerves are efferent and motor, and cause contraction of the muscles to which the nerves are distributed.

The *posterior* roots of the spinal nerves are afferent and sensory, and are distributed to the skin.

3. The functions of the liver are: (1) the secretion of bile, (2) the formation of glycogen, (3) the formation of urea and uric acid, (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material

The blood-vessels entering the liver are the hepatic artery and portal vein.

5. The mechanical uses of saliva are: (1) to moisten the mouth, (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste, (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition.

6. Gases which may be found in the stomach are:—Air, oxygen, nitrogen, hydrogen, carbon dioxide, marsh gas, and sulphuretted hydrogen.

7.

Arteries	Veins
Generally carry arterial blood	Generally carry venous blood.
Carry blood from the heart	Carry blood to the heart.
Do not collapse when cut	Collapse when severed.
Are found contracted and empty after death	Are not found empty after death.
The middle coat is the thickest	The external coat is the thickest.
Do not have valves	The medium-sized veins have valves.

8. The movements of the lungs are active in inspiration and passive in expiration.

9. The changes produced in the *air* by respiration are:

	Inspired Air	*Expired Air*
Oxygen	.21 per cent.	16.6 per cent.
Nitrogen	.79 per cent.	79 per cent.
Carbon dioxide	0.04 per cent.	4.4 per cent.
Other gases	Rare.	Often present.
Watery vapor	Variable.	Saturated.
Temperature	Variable.	That of body.
Volume	Varies.	Diminished.
Bacteria	Always present.	None.
Dust	Always present.	None.

10. Efferent or centrifugal nerves carry impulses away from the nerve centers. Afferent or centripetal nerves carry impulses to the nerve centers.

SURGERY.

1. In ligating the superficial femoral artery at its lower third the following structures are severed:—Skin, superficial fascia, fascia lata, fibres of sartorius, and the aponeurotic roof of Hunter's canal.

The anatomic relations of the artery here are:—*Anteriorly*, the structures just named and the internal cutaneous and long saphenous nerves; *posteriorly*, the junction of the vastus internus with the adductor longus and magnus, femoral vein; *externally*, vastus internus and femoral vein; *internally*, adductor longus and magnus.

9. In *hydrocele* the swelling is first noticed at the lowest part of the scrotum, and it increases in size slowly; it is tense, smooth, and fluctuates; there is no pain and no symptoms of inflammation; *it is translucent.*

In *orchitis* the swelling comes on more rapidly; it is very painful and also tender to the touch; the skin over the affected gland is red and shiny; *it is not translucent.*

OBSTETRICS.

3. Conditions that may require the induction of premature labor:—(1) Certain pelvic deformities, (2) placenta prævia, (3) pernicious anemia, (4) toxemia of pregnancy, (5) habitual death of the fetus toward the end of pregnancy, (6) hydatidiform mole.

4. Ectopic gestation is a pregnancy in which the ovum is developed outside of the uterine cavity.

Varieties:—Ovarian, tubal, interstitial, abdominal.

Diagnosis:—"When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*" (*American Text-Book of Obstetrics.*)

9. (a) The diameters and measurements of the female pelvis are easily remembered from the following table:

	Antero-posterior	Oblique	Transverse
Brim	4 inches	4½ inches	5 inches
Mid-plane	4½ "	4½ "	4½ "
Outlet	5 "	4½ "	4 "

(b) The fetal head has the following diameters: Occipito-frontal, occipito-mental, bitemporal, biparietal, suboccipito-bregmatic, trachelo-bregmatic, and mento-bregmatic. Of these, the occipito-frontal is 4 1-2 inches, the occipito-mental is 5 1-2 inches, and all the others are approximately 3 1-2 inches.

10. *Positive signs of pregnancy*:—(1) hearing the fetal heart sound; (2) active movements of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

Doubtful signs of pregnancy:—(1) progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix: (8) pigmentation and striæ; (9) morning sickness.

PRACTICE OF MEDICINE.

1. The following contraindications for ether and chloroform are from Hare's *Practical Therapeutics*: "*Ether* should not be used by inhalation in bronchitis or acute nephritis, because of its irritant properties; in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible.

"*Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

2. *Arteriosclerosis* is a condition in which the walls of an artery, especially the intima, become hard, dry, and thickened.

Etiology:—Syphilis, alcoholism, gout, Bright's disease, overeating, and excessive muscular exertion. It is not liable to occur in old age.

6. Immunity is the power of resistance of cells and tissues to the action of pathogenic bacteria.

Immunity may be acquired by:—(1) a previous attack of the disease; (2) inoculation, with small quantities of bacteria, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

9. *Opium poisoning*: *Symptoms*:—In opium poisoning there may be three stages: (1) a period of excitement, in which the patient is active, talkative, and has hallucinations; (2) a period of drowsiness, in which the patient is sleepy, but may be aroused; his face is pale, lips livid, pupils contracted; this passes into (3) the stage of coma, from which the patient cannot be aroused, the reflexes are abolished, the pupils are very contracted, the pulse is slow and irregular, and the respirations are infrequent and shallow.

Treatment consists in washing out the stomach, preferably with a dilute solution of potassium permanganate; ambulatory treatment, to keep the patient awake: artificial respiration is indicated, and strong coffee should be administered by the mouth or rectum; the bladder should be emptied by the catheter.

Strychnine poisoning: *Symptoms*:—"Strychnine produces a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five to six hours, usually within two hours.

"*Treatment*:—The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible." (Witthaus' *Essentials of Chemistry*.)

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.
Alabama*	W. H. Sanders, Montgomery	Montgomery..Sept. 1–6
Arizona*	Ancil Martin, Phoenix	Phoenix..October 7
Arkansas*	F. T. Murphy, Brinkley	Little Rock..October 8
California	Chas. L. Tisdale, 1870 Sutter Street, San Francisco	San Francisco.
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver..October 1
Connecticut*	Chas. A. Tuttle, New Haven	New Haven..Nov'ber 12
Delaware	J. H. Wilson, Dover	Dover..Dec'ber 10
Dis. of Col'bia	W. C. Woodward, Washington	Washington..October 10
Florida*	J. D. Fernandez, Jacksonville	Jacksonville..Nov'ber 20
Georgia	E. R. Anthony, Griffin	Atlanta..October 8
Idaho	J. L. Conant, Jr., Genesce	Boise..October 1
Illinois	J. A. Egan, Springfield	Chicago..October 23
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis..October 22
Iowa	Louis A. Thomas, Des Moines	Des Moines..Sept'ber 17
Kansas	T. E. Raines, Concordia	Topeka..October 8
Kentucky*	J. N. McCormack, Bowling Green	Louisville..October 2
Louisiana	F. A. La Rue, 211 Camp Street, New Orleans	New Orleans..October 15
Maine	W. J. Maybury, Saco	Portland..Nov'ber 12
Maryland	J. McP. Scott, Hagerstown	Baltimore..Dec'ber 3
Massachusetts*	E. B. Harvey, State House, Boston	Boston..Sept'ber 10
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Lansing..October 8
Minnesota	W. S. Fullerton, St. Paul	St. Paul..October 1
Mississippi	J. F. Hunter, Jackson	Jackson..October 8
Missouri	J. A. B. Adcock, Warrensb'g	St. Louis..Sept'ber 10
Montana*	Wm. C. Riddell, Helena	Helena..October 1
Nebraska	Geo. H. Brasb, Beatrice	Lincoln.
Nevada	S. L. Lee, Carson City	Carson City.
N. Hampshire*	Henry C. Morrison, State Library, Concord	Concord..January 14
New Jersey	J. W. Hennett, Long Branch	Trenton..October 22
New Mexico	B. D. Black, Las Vegas	Santa Fe..Dec'ber 2
New York	C. F. Wheelock, Unv. of State of New York, Albany	New York.. / Albany.. / Syracuse.. / Buffalo.. — October 1
N. Carolina*	G. T. Sikes, Grissom	Winston, Salem..May 1908
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks..October 1
Ohio	Geo. H. Matson, Columbus	Columbus..Dec'ber 10
Oklahoma*	J. W. Baker, Enid	Guthrie..Sept'ber 24
Oregon	B. E. Miller, Portland	Portland..January 7
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia / Pittsburg.. — Dec'ber —
Rhode Island	G. T. Swartz, Providence	Providence..October 3
S. Carolina	W. M. Lester, Columbia	Columbia..June 9, '08
S. Dakota	H. E. McNutt, Aberdeen	Mitchell..January 8
Tennessee*	T. J. Happel, Trenton	Memphis.. / Nashville.. / Knoxville.. — May, 1908
Texas		
Utah*	R. W. Fisher, Salt Lake City	Salt Lake City.October 7
Vermont	W. Scott Nay, Underhill	Montpelier..January 14
Virginia	R. S. Martin, Stuart	Staunton..Dec'ber 10
Washington*	C. W. Sharples, Seattle	Spokane..January 7
W. Virginia	H. A. Barbee, Point Pleasant	Clarksburg..Nov'ber 12
Wisconsin	J. V. Stevens, Jefferson	Milwaukee..January 14
Wyoming	S. B. Miller, Laramie	Laramie..Oct. 9

* No Reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

REQUIREMENTS FOR MEDICAL LICENSURE.

In the following table the States requiring of the candidate both a diploma from a recognized college and an examination are printed in roman; those requiring either a diploma or an examination, in italics; those requiring an examination only, in small capitals.

State	Fee	State	Fee
Alabama	$10.00	Nebraska	$25.00
Arizona	10.00	*Nevada*	25.00
Arkansas	10.00	New Hampshire	10.00
California	20.00	New Jersey	25.00
Colorado	25.00	*New Mexico*	25.00
Connecticut	15.00	New York	25.00
Delaware	10.00	North Carolina	10.00
District of Columbia	10.00	North Dakota	20.00
Florida	15.00	Ohio	25.00
Georgia	10.00	Oklahoma	5.00
Idaho	25.00	Oregon	10.00
Illinois	10.00	Pennsylvania	25.00
Indiana	25.00	Rhode Island	10.00
Iowa	10.00	South Carolina	10.00
Kansas	15.00	South Dakota	20.00
Kentucky	10.00	Tennessee	10.00
Louisiana	10.00	Texas	15.00
Maine	10.00	Utah	15.00
Maryland	15.00	Vermont	15.00
Massachusetts	20.00	Virginia	10.00
Michigan	25.00	Washington	25.00
Minnesota	10.00	West Virginia	10.00
Mississippi	10.00	Wisconsin	10.00
Missouri	15.00	Wyoming	25.00
Montana	15.00		

New York.—The subjects assigned to the new State Board Examiners are:—Anatomy, to Dr. W. S. Ely; Physiology, to Dr. R. H. Williams; Chemistry, to Dr. F. S. Farnsworth; Hygiene and Sanitation, to Dr. E. Beach; Surgery, to Dr. F. M. Crandall; Obstetrics and Gynecology, to Dr. W. W. Potter; Pathology, to Dr. W. S. Searle; and Bacteriology, to Dr. F. W. Adriance.

West Virginia reciprocates, under certain conditions with the following States:—District of Columbia, Georgia, Kansas, Kentucky, Michigan, Missouri, Nebraska, North Dakota, South Carolina, Tennessee, Virginia, and Wisconsin.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

AMERICAN POCKET MEDICAL DICTIONARY. Edited by W. A. NEWMAN DORLAND, A.M., M.D. 16mo, 578 pages, flexible leather. W. B. Saunders Co., Philadelphia.

PRACTICAL GYNECOLOGY. By E. E. MONTGOMERY, M.D., LL.D. Third revised edition, 8vo, 970 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia.

THE PRINCIPLES AND PRACTICE OF DERMATOLOGY. By WILLIAM ALLEN PUSEY, A.M., M.D. 8vo, 1021 pages, illustrated, muslin. D. Appleton & Co., New York.

CLINICAL PSYCHIATRY. By A. ROSS DIEFENDORF, M.D. New revised edition, 8vo, 562 pages, illustrated, muslin. The Macmillan Co., New York.

POSTOPERATIVE TREATMENT. By NATHAN CLARK MORSE, A.B., M.D. Second edition, revised and enlarged, 8vo, 499 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia.

LATERAL CURVATURE OF THE SPINE AND ROUND SHOULDERS. By ROBERT W. LOVETT, M.D. 8vo, 188 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia.

PROGRESSIVE MEDICINE. Quarterly, June 1, 1907. 8vo, 381 pages, illustrated, paper. Lea Brothers & Co., New York.

NEPHRITIS. By SEELYE W. LITTLE, M.D. 12mo, 134 pages, muslin. The Grafton Press, New York.

PRÉCIS DE TECHNIQUE. Par P. REDARD. 12mo, 591 pages, illustrated, muslin. F. R. De Rudeval, editeur, Paris.

HYGIÈNE COLONIALE. 8vo, 559 pages, paper. Librairie J. B. Bailliere et Fils.

MODERN METHODS OF DIAGNOSIS IN URINARY SURGERY. By EDWARD DEANESLY, M. D., B.Sc., etc. 12mo, 97 pages, illustrated, muslin. H. K. Lewis, London.

AMERICAN PRACTICE OF SURGERY. Vol. 3. Editors, JOSEPH D. BRYANT, M.D., LL.D., and ALBERT H. BUCK, M.D. 4to, 775 pages, illustrated, muslin. William Wood & Co., New York.

GYNECOLOGY AND ABDOMINAL SURGERY. Edited by HOWARD A. KELLY, M.D., F.R.C.S., and CHARLES P. NOBLE, M.D. Vol. 1, 4to, 851 pages, illustrated, muslin. W. B. Saunders Co., Philadelphia.

A LABORATORY MANUAL OF INVERTEBRATE ZOOLOGY. By GILMAN A. DREW, Ph.D. 8vo, 201 pages, muslin. W. B. Saunders Co., Philadelphia.

MEDIZINAL-BERICHTE ÜBER DIE DEUTSCHEN SCHUTZGEBIETE. 8vo, 266 pages, illustrated, muslin. Berlin, 1907, Ernst Siegfried Mittler und Sohn.

A MANUAL OF DISEASES OF THE NOSE, THROAT, AND EAR. By E. B. GLEASON, M.D., LL.D. 12mo, 556 pages, illustrated, flexible leather. W. B. Saunders Co., Philadelphia.

DISEASES OF THE RECTUM. By W. C. BRINKERHOFF, M.D. 12mo, 207 pages, illustrated, muslin. Orban Publishing Co., Chicago.

SIXTH ANNUAL REPORT OF THE METROPOLITAN WATER AND SEWERAGE BOARD, Jan. 1, 1907. 8vo, 253 pages, illustrated, muslin. Wright & Potter Printing Company, State Printers, Boston.

DISEASES OF THE INTESTINES AND PERITONEUM. By Prof. Dr. HERMANN NOTHNAGEL. Second edition, thoroughly revised. 8vo, 1059 pages, illustrated, muslin. W. B. Saunders Co., Philadelphia.

DISEASES OF THE STOMACH. By Dr. I. BOAS. 8vo, 730 pages, illustrated, muslin. F. A. Davis Company, Philadelphia.

THE PRACTICE OF OBSTETRICS. By American authors, Edited by CHARLES JEWETT, M.D. Third edition, revised and enlarged. 8vo, 820 pages, illustrated, muslin. Lea Brothers & Co., New York.

MODERN MEDICINE. Edited by WILLIAM OSLER, M.D. Vol II. 8vo, 828 pages, illustrated, muslin. Lea Brothers & Company, New York.

INTERNATIONAL CLINICS. A quarterly, by leading members of the medical profession throughout the world. 8vo, 312 pages, illustrated, muslin. J. B. Lippincott Co., Philadelphia.

TREATMENT OF THE DISEASES OF CHILDREN. By CHARLES GILMORE KERLEY, M.D. 8vo, illustrated, muslin. W. B. Saunders Co., Philadelphia.

DIE HYGIENISCHE-DIÄTETISCHE BEHANDLUNG DER SYPHILISKRANKEN. Von Dr. JULIUS MÜLLER. 8vo, 118 pages, paper. Verlag von August Hirschwald, Berlin, 1907.

DIE CHRONISCHE PROGRESSIVE SCHWERHÖRIGKEIT. Von AUGUST LUCAE. 8vo, 302 pages, illustrated, paper. Verlag von Julius Springer, Berlin.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 10, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	398	148
Diphtheria	211	22
Measles	221	20
Scarlet Fever	117	6
Smallpox	1	..
Varicella	14	..
Typhoid Fever	82	18

The Coincidence of Diseases.—Edmund Cautley believes that the coincidence and interaction of diseases rarely receive due attention. Thus errors in diagnosis, treatment, and prognosis are not uncommon. Acute diseases may be coincident and run their course without influencing each other to a recognizable extent. The severity of the illness, however, is generally increased. As an example, the concurrence of measles and diphtheria in the very young is almost invariably fatal. A more common coincidence of disease is that of acute illness in a patient affected by a chronic one. Variations in the course and duration of the latter are commonly noted under these circumstances. The beneficial effect of an attack of erysipelas on new growths has often been observed. The writer then gives a number of instances of the coincidence of diseases which have come under his immediate notice. Among these are two cases of typhoid plus paratyphoid fever, tuberculous plus cerebrospinal meningitis, and acute anterior poliomyelitis plus diphtheritic paralysis.—*The British Journal of Children's Diseases.*

Incipient Chronic Osteomyelitis.—A. Venot states that a careful differential diagnosis ought to be made in cases of this kind. Tuberculosis and syphilis should be excluded. To differentiate this affection from tuberculous osteitis is sometimes very difficult. When osteomyelitis develops without elevation of temperature it is not infrequently difficult to distinguish it from syphilis. If an examination of the patient for syphilis gives negative results the physician must not conclude absolutely that he is not dealing with osseous syphilis. Rheumatism also must be considered as well as osteosarcoma. Growing pains are in reality only a very slight form of osteomyelitis. Bone abscess, too, is but another form of chronic osteomyelitis, and the same treatment is indicated for both affections. Incipient chronic osteomyelitis is always difficult to diagnose because it is an osseous affection which develops without general phenomena, without the striking symptoms of acute osteomyelitis. This affection is a serious one because its evolution takes a long time. Slowly and insidiously it brings about in the bone disorders for which there is no other resource but amputation or disarticulation. Early diagnosis will save a limb and prevent months, and even years of suffering for the patient.—*Journal de Médecine de Bordeaux.*

Acidification of the Viscera as a Symptom of Death.—Ascarelli Attilio draws our attention to the difficulty of ascertaining whether death has really taken place, which has been recognized in Germany by attaching to every cemetery a mortuary room in which every body is retained for a certain number of hours before burial, while attached to it are instruments of precision which will give warning of the slightest movement. The author has made an extended series of experiments on dogs to ascertain whether the acidification of the tissues of the body, which takes place soon after death, cannot be made use of as an exact demonstration of death. He gives it as his conclusion that this acidification does take place uniformly in the tissues, so that its occurrence may be regarded as an infallible sign of real death. It is the first symptom of death appearing in thirty-five minutes after the cessation of the heart beats. The removal by means of a trochar of a small portion of the splenic parenchyma and testing it will show the presence of acidity. Acidity appears first in the spleen, kidneys, heart, and liver. The cause of death makes certain variations in the phenomena, but the rapidity of death has no effect on acidification.—*Bollettino della Regia Accademia Medica di Roma.*

LANDMARKS IN THE BILIARY AND PANCREATIC DUCTS;

PHYSIOLOGICAL, ANATOMICAL, AND PATHOLOGICAL.

By BYRON ROBINSON, B.S., M.D.,

CHICAGO.

A LANDMARK is a point for consideration—anatomical, physiological, and pathological. There are five significant landmarks in the biliary and pancreatic ducts, viz., (1) *Pelvis of the gall-bladder* (Cholecystitis Pelvis), Hartman's pouch; (2) *Cystic duct* (ductus cysticus); (3) *Intrapancreatic segment* of the bile duct; this is the portion of the common bile duct which courses through the head of the pancreas; (4) *Relation of Vater's diverticulum to the termination of the biliary and pancreatic ducts;* (5) *The single or multiple termination of the pancreatic ducts.* On the above five landmarks of the biliary and pancreatic ducts—physiological, anatomical, and pathological—depend many clinical phenomena. It may be remarked in general that the epithelium of the biliary duct is desquamated with the most marked facility of any duct, hence infection extends also with facility through the atria via the lymphatics.

1. *The Pelvis of the Cholecyst* (see IV in figs.) —In large numbers of gall-bladders there is a peculiarly formed pouch or funnel at the exit of the gall-bladder into the ductus cysticus. This gall-bladder

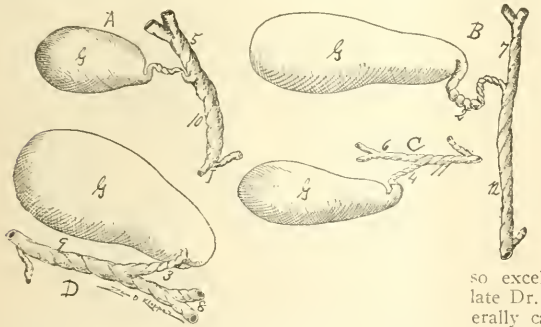

FIG. 1.—Represents four human biliary apparatuses injected with liquid paraffin and drawn from the dried specimen. The variability of the cystic duct is evident in: A, length; B, diameter. C, flexion at cholecystis pelvis; D, spirality; and in the angle of junction with hepatic duct; the location of entrance into the ductus hepaticus; number of Heister's valves; and the form and dimension of the gall bladder pelvis; 1, 2, 3, 4, ductus cysticus; 5, 6, 7, 8, ductus hepaticus; 9, 10, 11, 12, ductus choledochus.

reservoir is Hartman's pouch. He termed it the fossa Provesicalis. (Robert Hartman. German Anatomist, Berlin.) This pouch is an exceedingly important anatomical landmark because its funnel form harbors calculi with facility. Certain-shaped calculi, when once lodged in this reservoir-formed pelvis of the cholecyst, are dislodged with difficulty. The calculus may rotate, oscillate in this pouch like a ball and socket joint. Contractions of the gall-

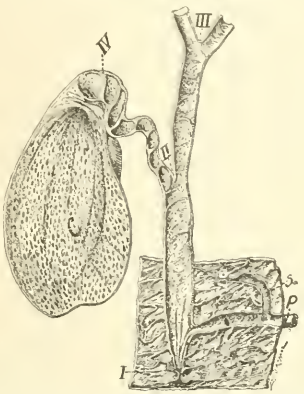

FIG. 2.—Drawn from a specimen injected with red lead mixed with starch. The bile duct and the pancreatic ducts were incised longitudinally and the material injected was evacuated from the ducts; then the interior of the ducts was sketched as a model by Z. Kloppor. Heister's valves are well demonstrated. The funnel form of Hartman's pouch is evident. The following letters and figures indicate identical matters in illustrations: I, Vater's ampulla; II, junction of ductus cysticus and ductus hepaticus; III, bifurcation of ductus hepaticus; IV, cholecystic pelvis; C, cholecystis; P, ductus pancreaticus (Hofman-Wirsung's); Sa, ductus accessorius pancreaticus (Santorini's); I to II, ductus choledochus communis; II to IV, ductus cysticus; II to III, ductus hepaticus.

bladder or vesicula bilis from calculus irritation or trauma may force the calculus more vigorously and violently into the pelvis. The gall-bladder pelvis or cholecystic pelvis is important pathologically because it is in this pouch that the calculus attempts to engage in the exit between the cholecyst and ductus cysticus, desquamating the epithelium, producing infection atria and causing the excruciating agonizing pain of gallstone. The hepatic calculus engages in the orifice of the ductus cysticus similar to the head of a child engaging in the aperture, pelvis, or proximal pelvic brim. There may be a ball valve joint present so excellently described by Courvoisier and the late Dr. Christian Fenger. The ball valve is generally caused by a spherical calculus of sufficient dimension (marble size) endeavoring to enter or engage in the gall-bladder pelvis; too great in dimension to enter the orifice of the ductus cysticus, so merely attempting to engage. The spherical calculus rotates and oscillates in the pelvis, inducing now obstruction and now allowing the bile to flow into the cystic duct—the trauma of which continually causes the fires of infection to migrate through the cholecystitis pelvis and cystic duct wall, begetting peripelvic and pericystic peritoneal adhesions by means of lymphangitis. With the spheroid or conical Hartman's pouch, practically occupied by a

spherical calculus, the chief damage is frequent recurring pain and desquamation of the epithelium

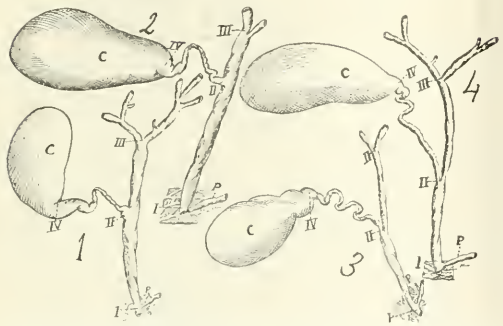

Fig. 3.—Represents four human biliary apparatuses drawn from injected dried specimens; practically each illustration represents the pelvis of the gall-bladder; note variations of biliary duct segments in form, length, diameter, spirality, and valves.

of the cholecystic pelvis producing consequent infection atria which give rise to the adjacent peritoneal

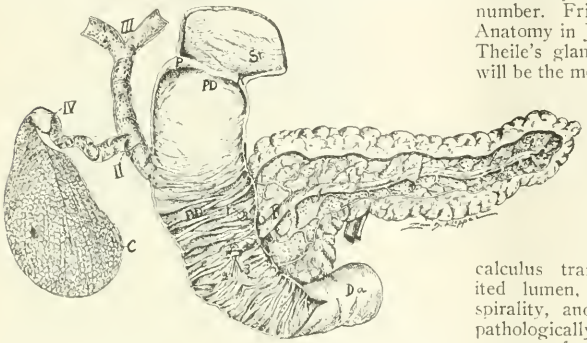

Fig. 4.—This illustration is drawn from a specimen of a healthy male, 74 years old, and presents: PD, the proximal 2½ inches of the foldless granular duodenal mucosa (practically the distal end of the stomach). Observe that DD, the vulvulæ conniventes (practically the proximal end of the enteron) begin immediately proximal to the entrance of the duct of Santorini, from which a probe projects; 2, probe projecting from Vater's ampulla and ductus pancreaticus (P); 3, probe projecting from Vater's ampulla and the choledochus (coursing dorsad to duodenal wall).

adhesions, the spider-web adhesions. It is a form of lymphangitis accompanied by peritoneal exudates

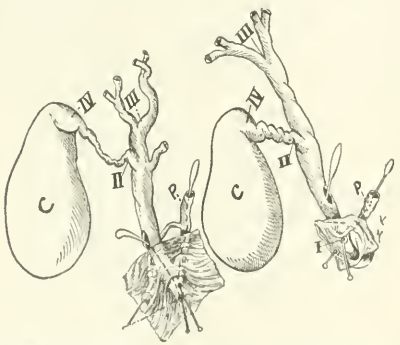

Fig. 5.—Two biliary apparatuses drawn from injected dried specimens, II to III, ductus cystieus; the cholecyst (C), ductus cystieus (II to IV), ductus hepaticus (II and III), and ductus choledochus (I to II) are in the position and relation of the living subject; the variations in the segments of the biliary and pancreatic segments are evident; note the separate and independent exit of the choledochus and ductus pancreaticus in the duodenum by the projecting probes.

which cause adherence of the vesicula bilis to adjacent organs in 40 per cent. of subjects (*e.g.* duodenum, gastrium, colon, omentum, kidney, pancreas). Fortunately the relative limitation or absence of Theile's glands in Hartman's pouch limits its facility in transmiting infection through its walls.

Frequently we find an hepatic calculus so firmly lodged, wedged, in the pelvis of the gall-bladder that it is impossible to dislodge it without fracturing. The cholecystis pelvis is located at the junction of the vesicula bilis and ductus cysticus. It is a marked flexion of the ductus bilis which enhances the difficulty and pain of calculus engagement in the orifice of the ductus cysticus. The flexion of the gall-bladder on the cystic duct at Hartman's pouch resembles the breast and neck of a swan, and is fixed in position by abundant powerful adjacent connective tissue.

The function of the gall-bladder pelvis is sensation, peristalsis, absorption, secretion. I was unable definitely to locate the presence of Theile's glands in the cholecystis pelvis, hence they must be limited in number. Friedrich Wilhelm Theile, Professor of Anatomy in Jena, Germany; 1801-1879. The fewer Theile's glands in the gall-bladder pelvis the less will be the means of conduction of infection through its walls. A pericholecystic lymphangitis is a frequent occurrence (40 per cent. of subjects).

2. *Cystic Duct* (Ductus Cysticus, see Figs. 2 to 4).—The cystic duct is one of the most important landmarks in the biliary channel, anatomically, pathologically, and physiologically. It is significant anatomically in calculus transportation on account of its limited lumen, its index-finger length, its marked spirality, and numerous valves. It is important pathologically on account of the painful traumatic passage of calculus and consequent frequent atria of infection, abetted in conducting infection through

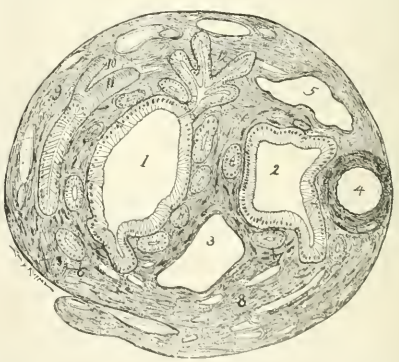

Fig. 6.—Glands of the Ductus Cysticus (Glands of Theile); cross-section of the ductus cysticus and ductus hepaticus at their bifurcation; from a girl of nine years old dying of sarcoma of the kidney; the epithelium was hypertrophied. 1, ductus cysticus; 2, ductus hepaticus; 3 and 5, veins (portal), 4, arteria hepatica, 6, glands of the cystic duct; 9, walls of the cystic duct; 8, walls of the hepatic duct; 10, arm of tubular or elongated gland; 11, tubular elongated gland; the cystic duct is surrounded by the compound gland, 12, and the tubular or elongated gland, 10 and 11; in the hepatic duct no crypt is shown because of the artist's oversight; the epithelium of this subject was hypertrophied, due to metastasis of the sarcoma from the kidney to the liver; the specimen is highly magnified; the glands of the bile ducts (Theile's glands) here present the fact that they may become infected in the ductus cysticus by trauma of calculus or infection; no doubt infection from Theile's glands explains chronic infection in the cystic duct wall and immediately adjacent structures, such as the peritoneum, *et.* surrounding lymphangitis

its walls by the presence of numerous Theile's glands. The ductus cysticus in 42 subjects measured in inches: length, maximum 2½, average 1½, minimum ¾; diameter, maximum ¼, average 1-12, minimum 1-16. The spirality of the ductus cysticus may present three distinct axial rotations. In 42 subjects Heister's valves numbered, maximum 10, average 7, minimum 3. (Lorenz Heister, German Anatomist, 1683-1758, Prof. in Leipzig and Amsterdam.) The cystic duct possesses a variation of three times its average length (1½ inches), a variation of four times its average diameter (1-12 inch), a variation one and one-half times its average number of valves (7), a marked variation of its spirality, a variation of the location of its exit to ¾ of the circumference of the ductus hepaticus, as well as a variation in its angle of entrance. The excruciating pain of a calculus passing through the cystic duct with maximum length (2½ inches), with maximum number of valves (10) projecting through half its lumen, with maximum spirality (3 axial rotations), with minimum diameter (1-16 inch), entitles the cystic duct to the dignity of a landmark in the biliary passages—a point for consideration, anatomical, physiological, and pathological. The above may seem a simple statement, but it required 42 autopsies with detailed labors to substantiate it. The mucosa of the cystic duct is more liable to trauma from a calculus and consequent atria of infection than any other segment of the ductus bilis on account of its limited lumen and its projecting mucous valves. The glands of the bile duct, Theile's glands, are numerous in the ductus cysticus and may harbor and transmit infection. The cystic duct permits the passage of air and fluid from the vesicula bilis to the duodenum, but is generally impermeable to a probe. The function of the ductus cysticus is sensation, peristalsis, absorption, secretion. The cystic duct may be obliterated by ligature or disease which excludes the function of the cholecyst and the subject lives practically healthy similar to animals who possess no gall-bladder, such as the horse, camel, elephant, and deer.

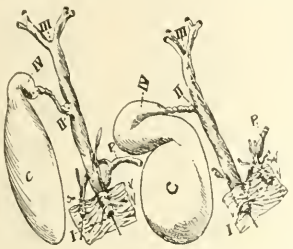

Fig. 7.—Two biliary apparatuses drawn from distended dried specimens; Sa, Santorini's ducts are patent in each specimen; the right-hand figure has a swan-shaped cholecyst (C); note spirality of ductus cysticus and typical Hartman's pouch.

3. *Intrapancreatic Segment of the Bile Duct* (see Figs. 9, 10, 11, 13, 17, 20, 21).—A significant landmark in the ductus chaledochus communis is that segment which passes through the caput pancreaticum, the pancreatic head. From my examinations at autopsies I should judge that the bile duct coursed obliquely through the head of the pancreas in 90 per cent. or more of subjects. The choledochus is imbedded in the pancreatic substance for perhaps ¾ of an inch of its length and so firmly surrounded by pancreatic substance that it may be difficult to liberate the duct by blunt dissection, and pancreatic incisions may be accompanied by alarming hemorrhage. I shall term this the intrapancreatic segment of the common bile duct. It is not only a significant anatomical landmark from its relations with the pancreas, but is also an important pathological landmark of the common bile duct. The pathological signification of the passage of the choledochus through the pancreatic head is that the pancreas may and actually does become infected through the duct. It is common in autopsies, with hepatic-duct infection, to be able to palpate an induration of the segment of the pancreas through which the common bile

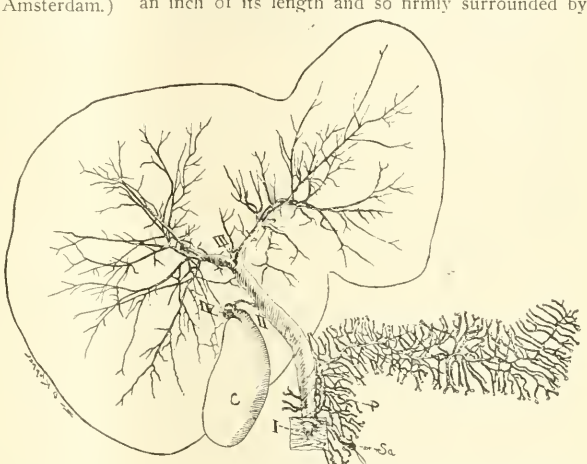

Fig. 9.—Roentgen ray of ductus bilis and ductus pancreaticus; subject had advanced hepatic sclerosis; II to III, ductus cysticus extremely contracted in dimensions, especially its diameter; its spirality and valves were so marked and rigid that it would not allow the passage of a calculus larger than a duck shot; observe the intrapancreatic segment of the bile duct

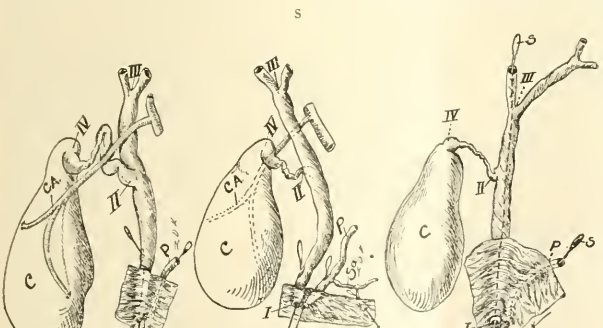

Fig. 8.—Three biliary apparatuses drawn from distended dried specimens; they are in natural position; the cystic artery (C A) is drawn in natural position, in two specimens on the left; the ductus bilis and ductus pancreaticus have each a separate exit in the duodenum (see probes); observe typical Hartman's pouch (IV), with marked spirality and valves of the ductus cysticus (II to IV).

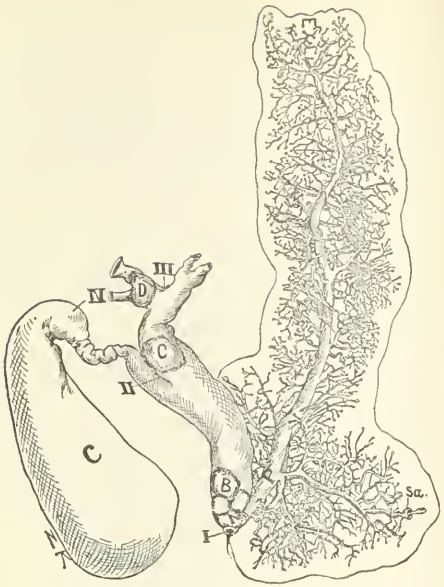

FIG. 10.—Roentgen ray of ductus pancreaticus and part of ductus bilis; I to II enormously dilated ductus choledochus containing four hepatic calculi at (A-B); II to IV ductus cysticus dilated to 1-3 of an inch in diameter and still preserving six marked Heister' svalves; IV a dilated Hartman's pouch; C, choleeystis dilated; II to III ductus hepaticus with large calculi at (C), also a calculus (D) in a minor ductus hepaticus; in this case the caput pancreaticum was indurated, owing to infection through the parietes of the choledochus; though suppuration existed at the location of the calculus (A-B), I was unable to detect pathological conditions in the pancreatic duct; the choledochus and pancreatic ducts opened separately on the floor of Vater's ampulla; observe the intrapancreatic segment of the bile duct

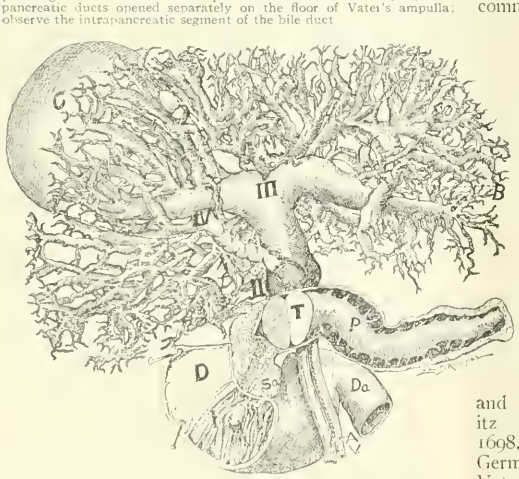

FIG. 11.—Carcinoma completely obstructing the biliary and pancreatic ducts in the intrapancreatic segment; the picture is drawn from an x-ray of the enormously dilated biliary passages, the biliary ducts (omitting the gall-bladder, which was three to four times its normal dimension) had a capacity of 32 ounces, i.e. about six or seven times the usual capacity, the ductus communis choledochus was over 1½ inches in diameter, the pancreatic duct admitted the index-finger. The man, 69 years old, a giant in stature, weighing some 250 pounds with ordinary limited fat, lost 115 pounds in weight during his last three months' illness. The ductus cysticus, extending from II to IV, had seven Heister's valves and its lumen would admit a lead pencil only. At B, the biliary ducts were deficient within the liver substance, but were really dilated on the surface, T, the carcinoma (divided with the scalpel), completely obstructing the lumen of the biliary and pancreatic ducts of the intrapancreatic segment; there was enormous gastro duodenal dilatation from the compression of the transverse duodenum by the superior mesenteric artery (A) and vein (V). D, foldless, granular, proximal 2½ inches of the duodenal mucosa, I, entrance of ductus communis choledochus in the duodenum, both ducts had their exit on the floor of Vater's ampulla, the probe indicates Vater's papilla. Sa, duct of Santorini with projecting probe. P, duct of pancreaticus enormously dilated, the ductus communis choledochus and ductus pancreaticus, located between the carcinoma and Vater's diverticulum were normal. Da, is the normal-sized duodenum located distal to the compressing superior mesenteric vein (V) and artery (A); observe the vast dilatation of the duodenum proximal to the superior mesenteric artery. (A) and vein (V). I secured this rare specimen at an autopsy through the courtesy of Dr. Charles O'Bryne

duct courses. The choledochus communis becomes attacked by catarrh, its epithelium becomes desquamated, infection, which gradually penetrates its wall, passes into the abundant glandular ductus bilis, and eventually infects the connective tissue and parenchmya of the pancreas—ending in pancreatic infection, induration, hypertrophy, or atrophy which may compromise not only the lumen and parietes of the choledochus communis but also the lumen and parietes of the ductus pancreaticus; a pericholedochus lymphangitis arises. Compromising of the hepatic or pancreatic ducts signifies retention and reabsorption of bile and succus pancreaticus.

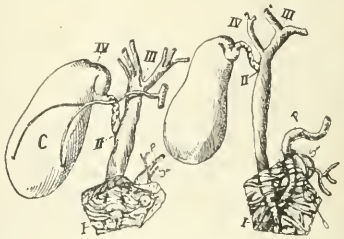

FIG. 12.—These specimens show the relation of Vater's ampulla to the choledochus, *i.e.* both ducts have their exit on the floor of Vater's ampulla, the usual arrangement, two biliary apparatuses drawn from dried distended specimens; the relative positions of the ducts are natural, (Sa) Santorini's duct in each specimen is patent.

This anatomical arrangement of the intrapancreatic segment of the bile duct explains the clinical relation of the hepatic ducts to the pancreas. The intrapancreatic segment of the ductus choledochus communis may infect the caput pancreaticus. This is the key which unlocks the information that the head of the pancreas is so frequently diseased—induration, hypertrophy, neoplasm. The cauda pancreatica, so frequently indurated, is perhaps infected, chiefly from the colon, or from the stomach or ureteral pelvis.

4. *The Relation of Vater's Ampulla to the Termination of the Biliary and Pancreatic Ducts* (see Fig. 1, also projecting probes).—The most significant anatomatical and pathological landmark of the biliary and pancreatic ducts is Vater's diverticulum (Abraham Vater, German Anatomist, 1684-1751, Prof. in Wittenberg). Vater's ampulla possesses the shape of an acorn with a single opening at its free end and two openings at its attached end. The two basal orifices of this bulb-shaped diverticulum or bladder-formed reservoir are those of the biliary duct and pancreatic or Hofman-Wirsung duct (Moritz H. Hofman, German Anatomist, 1622-1698, Prof. in Altdorf; and John George Wirsung, German Anatomist, 1643-died? Prof. in Padua). Vater's ampulla resembles the cloaca with the ureteral, vaginal, and rectal orifices opening into it or the marsupium of the marsupiala—a kangaroo pouch with the mammary nipples opening into it. The common bile duct and pancreatic duct seldom coalesce, unite, or blend; however, they usually exit separately, independently, on the floor of Vater's ampulla. The duodenal orifice of Vater's cone-shaped ampulla possesses the most limited lumen of the extrahepatic biliary channel. Vater's ampulla measures about 1-16 of an inch in length from apex to floor, and about 1-16 of an inch in diameter at its duodenal orifice. It requires some 20 serial transverse sections to extend from apex to floor of Vater's ampulla.

Anatomically, Vater's diverticulum is significant as it receives two separate important ducts—the

biliary and pancreatic—from the maximal glands, liver, and pancreas. Physiologically, Vater's diverticulum is significant, as it serves as a bladder-formed reservoir to mix the biliary and pancreatic fluid previous to their entrance into the duodenum. It is a physiological reservoir. Mixing biliary and pancreatic fluid in the diverticulum Vateri trebles their power of digestion. Pathologically, Vater's ampulla is significant, as it serves as an atrium of infection for the hepatic and pancreatic glands via the tractus intestinalis. Vater's ampulla is a dangerous location to harbor a calculus (hepatic or pancreatic), as it induces catarrh and infections from its trauma, desquamating epithelia, to travel toward the liver or pancreas. However, my observation in autopsies has been to the effect that hepatic calculus in the vast majority of subjects becomes lodged in the common bile duct immediately proximal to Vater's ampulla, and in this dilated locality of the common bile duct it does not disturb the free flow in the ductus pancreaticus. The knowledge of the anatomical fact that, in the vast majority of subjects, the biliary and pancreatic ducts possess an exit separately and independently on the floor of Vater's diverticulum, explains why disease processes in either duct affect only the duct actually involved, *i.e.* each duct is independently diseased, and seldom does hepatic and pancreatic disease occur coincidently except from excessively large calculus or neoplasm (see Fig. 11).

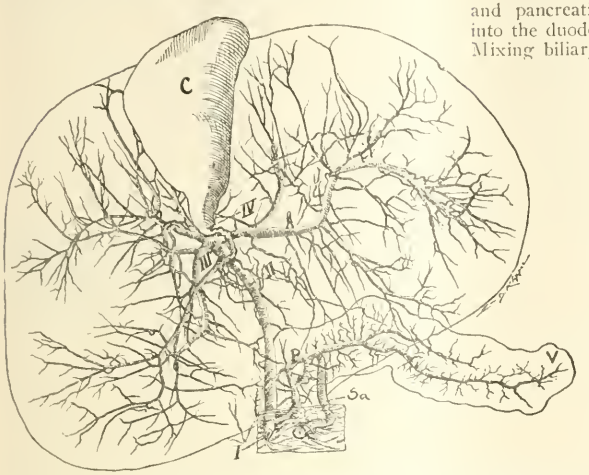

FIG. 13.—A Roentgen ray picture of the ductus bilis and ductus pancreaticus; this specimen shows the usual relation of the ductus choledochus and ductus pancreaticus having their exit on the floor of Vater's ampulla; note that the ductus pancreaticus is bifurcated; the intrapancreatic segment of the bile duct is dilated and hypertrophied.

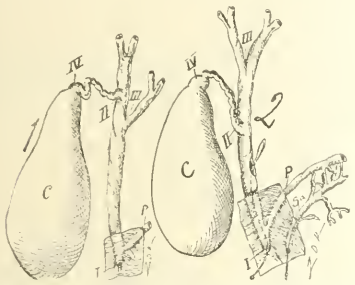

FIG. 14.—The biliary apparatus in usual relative position; drawn from dried distended specimens; these cuts show the usual relations of Vater's ampulla; I, presents the ductus cystic entering the biliary duct proximal to the bifurcation of the hepatic duct. 1, the ductus cysticus entering tbibiliary duct proximal to the bifurcation of the hepatic duct: 2, extensive anastomosis between Santorini's duct (Sa) and the Hofman-Wirsung duct.

5. *The Single or Multiple Terminations of the Pancreatic Ducts* (see Sa. or projecting probes in figures).—The single or multiple terminations of the ducts of the pancreas is a significant landmark physiologically and pathologically. The pathological signification is exposure to infection from the tractus intestinalis and the occurrence of calculus. The physiological signification of Santorini's duct is that it may act vicariously for the Hofman-Wirsung duct in case of accident. There are four kinds of terminations of the pancreatic ducts: (1) The usual termination for the ductus pancreaticus (Hofman-Wirsung's) is to exit separately independently in the base of Vater's ampulla (see Figs. 1, 2, 3, 4, 7, 9,

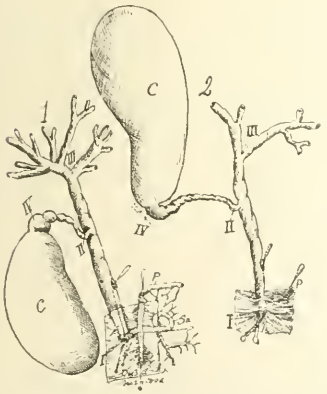

FIG. 15.—Two biliary apparatus drawn from dried distended specimens; the figure on the left is in natural positional relations; note that (Sa) Santorini's duct with a peculiar loop possesses an exit at the floor of Vater's ampulla in conjunction with that of the choledochus, while the regular ductus pancreaticus (p) has an exit at a distance from Vater's ampulla; Hofman-Wirsung's and choledochus possess separate, independent exits.

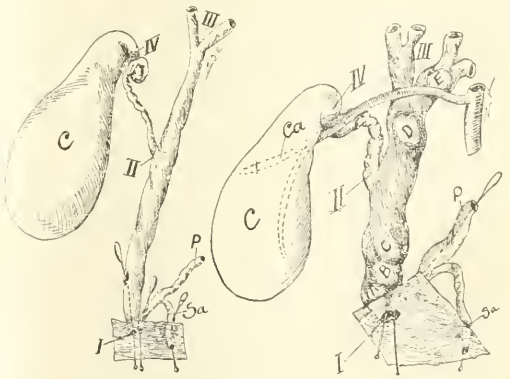

FIG. 16.—Two biliary apparatus drawn from distended dried specimens which are in natural position; the specimen on the right is pathologically dilated from calculi (A, B, C, D, E) in the ducts. Ca, cystic artery; the hepatic and pancreatic ducts have separate and independent exits in the duodenum as indicated by the projecting probes; also Sa, Santorini's ducts are patent in each specimen.

10, 11, 12, 13, 14, 18, 19, 20). (2) Another method of exit for the ductus pancreaticus is to terminate,

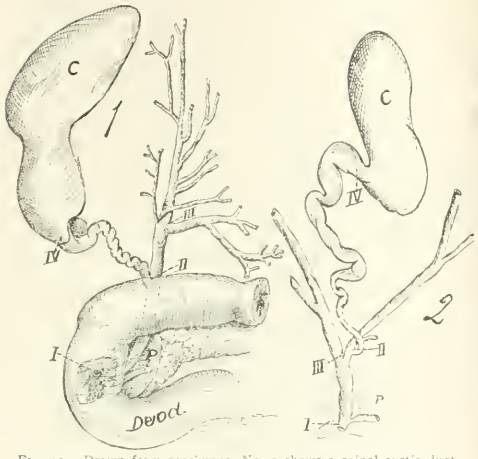

FIG. 17.—Drawn from specimens. No. 1 shows a spinal cystic duct and separate exits for choledochus and ductus pancreaticus; No. 2 is drawn from a dried injected specimen of a mountain lion weighing about 125 pounds; note the peculiar cystic duct, its form, exit, spirality and length, in the lion.

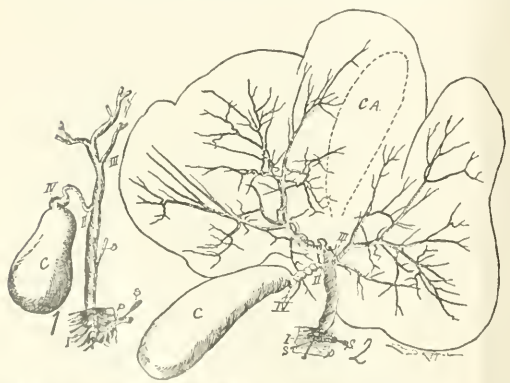
separately and independently in the duodenal mucosa (see Figs. 5, 8, 15, 16, 17 (1), 21). (3) The ductus

FIG. 18.—Biliary apparatus of man (left) and of monkey (right), drawn from injected distended specimens; No. 2, Ca, represents the original location of the cholecyst in the right-hand figure (monkey), dorsal view of monkey.

pancreaticus accessorius (Santorini's—Giovanni Dominico Santorini, Italian Anatomist, 1681-1737,



[illegible] from injected dried specimens [illegible] Drawn from Roentgen ray pictures, CA represents [illegible] location of the cholecyst; independent and separate exits [illegible] and ductus pancreaticus.

Prof. in Venice) possesses a separate independent exit within a distinct but varying distance from that of the ductus pancreaticus. Two pancreatic ducts occurred in each one of the forty-two subjects here reported, although it is not indicated in each of the

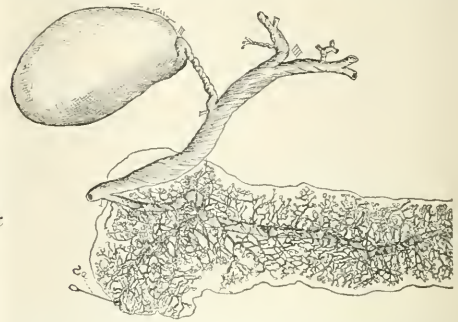


FIG. 20.—Roentgen ray picture of ductus pancreaticus and part of ductus bilis; II to III ductus cysticus, ventral view; observe that the intrahepatic segment of the biliary duct courses external to the pancreatic ducts but not to the substance of the gland.

illustrations. (4) An accidental substitution of the ductus pancreaticus (Hofman-Wirsung) for the

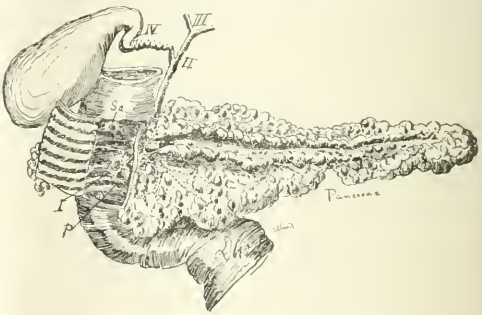

FIG. 21.—Specimen containing pancreatic calculus, from a post-mortem; man about 40 years; I to II, ductus choledochus; II to III, ductus hepaticus; III to IV, ductus cysticus; Sa, ductus pancreaticus accessorius; p, separate exit of ductus pancreaticus in duodenum; a calculus ¾ inch in length and 1-6 inch in diameter is incarcerated in the duct of the caput pancreaticum at P; the calculus of the pancreatic duct projects into the lumen of the duodenum; also six calculi lay in the ductus pancreaticus as noted in sketch; the pancreas was in an advanced stage of suppuration and fatty degeneration; this specimen was kindly presented to me by Dr. A. M. Stober; B. J. Beuker sketched it for me from the pathological laboratory of the Cook County Hospital.

ductus accessorius pancreaticus (Santorini's) may occur. In other words, the terminations of the chief and accessory pancreatic ducts may be reversed. (See Fig. 15 [1].)

There may be two pancreatic ducts (Hofman-Wirsung and Santorini) opening separately and independently on the duodenal as well as a separate independent orifice for the choledochus. The signification of two pancreatic ducts with separate exits is provisional, as if one becomes obstructed the other may serve vicariously. The termination of any duct in the tractus intestinalis is of vital significance pathologically, as it may serve as an atrium of infection—pathogenic, bacteria, calculus. However, the pancreas appears to be the most powerfully resistant and healthy organ in the abdomen. In hundreds of autopsies it has appeared to me to present fewer pathological conditions than any other abdominal viscus. Hence the ductus pancreaticus will preserve similarly healthy conditions. The common remark of the pathologist subsequent to a longitudinal incision through the pancreas is "negative." The chief induration of the pancreas occurs first in

the cauda and second in the caput (from bile duct infection). In all (42) of our reported specimens there were present two pancreatic ducts. In injecting the ductus pancreaticus and the ductus accessorius (Santorini's) it was found they functionated in some sixty per cent. of subjects. Hence perhaps the pancreatic ducts may assume vicarious function in one-half of subjects (fifty per cent.). The location of the exit of Santorini's duct may be at variable distances from Vater's ampulla, ventral, dorsal, distal, or proximal to the exit of Vater's diverticulum. Injections from the duodenum into Santorini's duct will pass into the Hofman-Wirsung duct and vice versa in perhaps fifty-five per cent. Hence either Santorini's duct or Hofman-Wirsung's duct may act vicariously for the other in case of occlusion. The function of the pancreatic ducts is sensation, peristalsis, absorption, secretion. The pancreatic ducts possess numerous glands of Theile.

REPORT ON TWO HUNDRED CHARITY CASES OF PULMONARY TUBERCULOSIS UNDER SANATORIUM TREATMENT AT LOS ANGELES FROM 1903 to 1907.*

By W. JARVIS BARLOW, M.D.

LOS ANGELES, CAL.

In reporting these two hundred cases of tuberculosis emphasis must be laid upon the fact that the sanatorium in Los Angeles where these were treated has taken patients in all stages of the disease, and the deductions drawn from the records show that ninety-two per cent. were beyond the first stage. Much has been shown this association of what can be done with the early or incipient cases; the purpose of this report is to bring to your notice what can be done with advanced cases. It must be remembered that the cases are taken from the poorer walks of life, yet the majority of them are refined people, the greater number single men and women on small salaries, with indoor occupation, having come to California in search of health, with funds exhausted and facing the impossible task of supporting themselves.

It is evident, and has not been too often said, that the best results are obtained by putting patients under sanatorium treatment at the earliest signs of disease. But another fact is that good results may be sometimes obtained by properly caring for those advanced in the disease. One is often astonished at the remarkable improvement that an advanced case, given up, makes when conditions have been made favorable. We must always remember, too, that in the fight against tuberculosis it is the advanced cases in poor housing which are the greatest source of danger to others. It is difficult to estimate the lives that may be saved by isolating these poor, advanced cases, who are shut out from most of the charitable sanatoria.

The majority of the patients discharged as improved have again become wage earners, and in daily life must carry the gospel of right living to others.

The plan working best is not to take the poor absolutely free, but make a charge of $5, which includes everything, even the washing and mending—often clothes. This $5 is usually given by other charitable funds, societies, unions, or brotherhoods, from which the case is referred.

*Read at the meeting of the American Climatological Association, Washington, 1907.

* Two patients under starred headings—no record (N. R.). One patient—non-tuberculous—on first hundred

For some account of the management and care of these cases it is a pleasure to refer to the paper presented you last year by Dr. Bonney on "The Care of Advanced Cases." Our method has been much the same through the three and a half years covering the treatment of these two hundred cases. The method of feeding has varied in individual cases, digestive disturbances treated with selected diet; in general, raw eggs and olive oil are given to each patient immediately after each meal, beef juice between meals. The olive oil might stand in the place of cream recommended, and to us has the advantage of being less expensive. Eggs and milk between meals are only given to those who cannot for some reason take the ordinary meals.

In regard to comfort Dr. Bonney strikes a keynote. We have also been impressed with the necessity for making these patients absolutely comfortable physically, and contented mentally; the surroundings attractive to ear and eye, giving some form of entertainment. Two phonographs are kept in constant use and often the piano. Musicals are given by local and Eastern artists interested in this work.

Outdoor Treatment.—The same principle of comfort applies to sleeping outdoors, and in Los Angeles there is no night so cold that, when properly protected, patients may not with comfort sleep in the screened room or porch. No tents have been used for any of the patients. The arrangement and general appearance of the cottages used are here shown. Although there is nothing new in the plan, these cottages are so arranged for fresh air that the patients who show improvement are practically in the open the whole twenty-four hours. The climate throughout the year is such that no heat in the cottages is required. There is no heat provided, and such is the training derived from the older patients that never has one asked for any heat in the sleeping rooms. A separate building, the infirmary, used for the progressive cases, is of course provided with heat, and so are the detached dining room and baths. The cottages each contain two rooms for two patients, each room 12x14 feet, with a porch on three sides five feet wide, two sides of screen to each room, screen under the eves, and a ventilator in the ceiling. There are so few rainy days throughout the year that another objection to the small cottage plan is overcome, and the expense is not increased. The average number of days that it rained each year for the past three years was thirty-four; the year from September, 1905, to September, 1906, showed only thirty days; next year's report will be higher. The average number of clear, cloudless days in three years was 212. The past year to September, 1906, it was 264; the average number of cloudy or partly foggy days was 101. The porches are so arranged that patients can be either in the sun or shade the entire day, depending upon his own comfort. It is a satisfaction to feel that others of this Association are opposed to keeping patients exposed to the rays of the sun when this produces discomfort.

The two hundred cases are individually recorded under separate headings, the classification of cases and results used is that in connection with Turban's scheme, and that proposed by the committee on nomenclature of the National Association.

Time will not be taken to discuss this, but the cumbersome details will be published for those interested. Remarks will be confined to the averages for the first and second hundred, as shown by the table here given.

In the whole average there are more males than females. There is room for an equal number of men and women at the sanatorium, but many more men than women make applications. Fifty-seven per cent. of the two hundred admitted were men, but the forty-three per cent. of women really means that the greater percentage of women applicants were admitted, since there is no place provided for these cases other than the County Hospital, to which very few women will go. Of the sixty per cent. that were American born, three per cent. were Californians.

There is a large proportion of foreigners, forty per cent. of the total number, the average time for residence in Los Angeles being five years. All kinds

of occupations are represented, the greater number clerks on small salaries; professional people not a few; physicians, clergymen, missionaries, artists, and actors, butchers, shoemakers, and stonecutters. Mark that eighty-two per cent. of these patients had followed some indoor occupation; only sixteen per cent. outdoor employment, under which list were put sailors, laborers, painters, soldiers, physicians, etc. Where it seemed in a few instances doubtful as to in- or outdoor occupation, the cases were placed on the outdoor list.

It is interesting to note that about sixty-six per cent. showed no family history of tuberculosis; in each group of fifty the greatest percentage showed no tuberculosis family history. Part of this may be explained by the fact that a few of the patients could give no satisfactory family history.

The prior duration of the disease has been shown to be a little more than two years, but it must be remember that this has been compiled from the patients' statements, and it has so often been found that the patients were unaware of the existence of the disease until it had reached an advanced stage that it would seem that this two years' duration is surely under- rather than overestimated. It is a significant fact that the average gain in weight in all patients was seven pounds, while the average loss was 5 9-10 pounds, but the tables show that the weight on discharge is only about 4½ pounds' gain, because these include the patients who died at the sanatorium. The best gain in three months of a far-advanced case was 22¾ pounds; another far-advanced patient gained 20 pounds in two months. Although the pulse, temperature, and respiration do not show marked change between admission and discharge, it must be remembered that the worst cases are included in this summary.

The average duration of treatment for the total number has been somewhat over three months. This is, of course, a smaller average than would be if one simply reported on the early cases, or even those that do well, for the latter cases are kept six months or more, so that the total average of duration of treatment is reduced on account of the bad cases, many dying after a few weeks' time, or even less.

The plan carried out in regard to the advanced cases has been to give each a trial of three months, and if the case showed progression arrangements have been made to send the patients to a place where family or friends could care for them until the end came. Many of these cases have been sent to their homes in eastern or foreign parts. The sanatorium is not yet in the financial condition to care for such cases indefinitely. Those that the sanatorium has been obliged to keep to the end are cared for in a separate building called the infirmary, isolated from the more favorable cases. The advanced cases which make a marked improvement and begin running normal temperatures are placed in the cottages above referred to, so that irrespective of the stage there is no difference made in the cases doing well.

Out of the first 100 cases 93 showed on admission the second and third stages, 62 2-5 per cent. of which showed progression or died; of these 93 cases 37 3-5 per cent. improved.

Out of the second 100 cases 91 were admitted in second and third stages, 45 per cent. showed progression or died, 55 per cent. improved.

To sum up the total 200 cases, 46 1-5 per cent. of the second and third stages showed a marked improvement. Many of these patients discharged improved became wage earners immediately. The few cases that were admitted in the first or incipient stage, that is, 13 or 6½ per cent., were all discharged as arrested or apparently cured, as well as three per cent. of those admitted beyond the first stage.

Summary.—Running a sanatorium in the way above stated does not make as favorable a report as a statement made from one where only early cases are admitted; but from the humanitarian standpoint and in view of the campaign against the spread of tuberculosis this report will, to its favor, bear critical investigation. That 46 1-5 per cent. of the advanced and far-advanced clinically recorded, or second and third stages anatomically, could, after being entirely incapacitated, so improve as to go

home, resume their duties, and many become wage earners, is worthy of recognition. The subsequent history of these will be interesting for a later day. Many are known to have become worse and died, some are living in tents in the country, others after six to twelve months are still doing light work for an existence.

The great difficulty lies in the fact that many of these patients must necessarily return to their wretched surroundings and life of privation. If, on the other hand, this difficulty could be removed and the same patients kept under proper supervision with sufficient means for their care many could go on and reach an arrested condition.

If financial conditions and housing capacity enabled us to give these patients indefinite sanatorium treatment, the ultimate results would seem to justify the care of these undesirable cases.

THE LOCAL TREATMENT OF CANCER.

By ROBERT BELL, M.D., F.F P.S.,
LONDON, ENGLAND.

During the period, fifteen years, that I have devoted to the study of the natural history of the cancer cell, I have convinced myself that though apparently little altered in character or appearance from its healthy progenitor, yet it is distinctly more depraved in its habits, and has lost considerably in vital energy. In short, it is of intrinsically weaker constitution than the normal cell from which it sprung. Notwithstanding this fact, however, it possesses the power, by contact with its environment, so to weaken this as to render it susceptible to attack and eventually to destroy and make a prey of it. There is one thing worthy of note, however, with regard to the development of cancer; this is that, though the tumor formed by the aggregation of these morbid cells is to all intents and purposes a foreign body, surrounded by more or less healthy tissue, yet it does not act as any other foreign body would do, by setting up inflammatory action and eventually suppuration and sloughing of the surrounding tissue, in Nature's endeavor to get rid of it. On the contrary, no effort would appear to be forthcoming to get quit of the incubus, and so the surrounding cellular tissue is gradually victimized, and succumbs to the cannibal propensities of the adventitious cells.

The reason for this forbearance in these circumstances is that, though a corrupt colony has been established within what otherwise is a healthy community, this colony is composed of units which, though assuming a new rôle of existence, are altered very little in feature from their law-abiding neighbors. In other words, they are composed of living tissue, differing little from that in their immediate vicinity, except in the important points, that (1) they have become intrinsically weaker, and therefore, when due precautions are taken, may be destroyed, while the normal tissue is possessed of sufficient vitality to enable it to resist the destructive effect of the agent employed in our efforts to demolish the morbid structure, and that (2) though amply supplied with blood-vessels, cancerous tumors are devoid of nerves. In consequence of this they are painless in themselves, and give rise to pain only by exerting pressure upon the surrounding parts, or by the erosions they produce in the later stages of their existence. It will be obvious, therefore, that were it possible to set up an active inflammatory process in malignant growths, this might be made to proceed to such an extent that it would prove destructive to the cancerous tissue, and also to that in its immediate proximity, which has had its vitality reduced by contact with the morbid structure. Thus we should be enabled to succeed in eradicating the disease for the time being, but I doubt very much if we could, by these measures alone, succeed in preventing recurrence of the malady, unless simultaneously we were to adopt a line of treatment which would remove those factors which had, prior to the incidence of the local manifestation of the disease, been insidiously at work undermining healthy cell metabolism. No; my conviction is this line of treatment will, as a rule, be doomed to failure, just as the knife has proved useless, unless measures be also adopted which will tend to reestablish those laws which have been so long disobeyed, and to the non-observance of which the mischief has been due. Dietetic and hygienic treatment must go hand in hand with any method that may be adopted in dealing with the local trouble if complete success be aimed at. Otherwise the relief will, I fear, prove to be only temporary.

As I have frequently averred, a cancer cell in many points still retains the characteristics of the normal cell, from which in the first instance it has its origin. But it certainly has ceased to take cognizance of those physiological laws which, in its normal condition, regulated its cycle of life. It has ceased to be under the domination of those laws and has become a law unto itself. It has also ceased to derive its nourishment from its natural source of supply, and in consequence has suffered in its vitality, though perhaps not in its activity, just as man or any other animal suffers by indulging in a diet which was never intended for him or it. Notwithstanding this, and paradoxical as it may appear, the cause of this degeneracy in the cancer cell consists in a vitiated condition of the blood stream, which is therefore precluded from supplying wholesome nutriment to the various tissues of the body, upon the purity of which their healthy functional activity depends. And, to speak figuratively, certain cells in consequence rebel and commence to seek for nourishment elsewhere, and so, from what appears to be actual necessity, become cannibals. Fortunately, however, this change of diet, though tending to make them more rapacious, succeeds at the same time in reducing their resisting power to certain agents, against which the normal cell is, comparatively speaking, immune. It is this knowledge which promises that we shall be enabled to employ irritants, but not caustic in their effect, which, though not strong enough to destroy the vitality of a normal healthy cell, will succeed in killing those that are diseased. For many years I have been experimenting on these lines, and with no little success, but unfortunately this local treatment is apparently applicable only to epitheliomata so far, though I have no doubt that eventually scirrhus will also be found amenable to its influence. As may be readily inferred, it is essential that the irritant employed must not be of a poisonous or caustic nature. A vegetable substance, therefore, is to be preferred, and one that, if absorbed, will not prove injurious to any extent.

We are all aware of the effect a mustard plaster produces upon the epithelial cells of the skin. Though, if kept on long enough, it kills the superficial layer, yet it does not prevent their speedy replacement, while the pain produced very soon passes off when the irritant is removed. But I think we have a better agent than mustard for our purpose in an infusion of capsicum pods, the strength of which can be easily regulated. Of course, the application of such a liquid will always prove painful for a time afterwards, especially round the margins of the dis-

cased tissue, but it is essential that this be included, so that none of the affected area be missed. The pain, however, can be mitigated considerably by a previous application of a 2 per cent. solution of cocaine, which I am inclined to think rather aids than retards the destructive effect upon the morbid cells. The application should be made at least once a day, and I have seen instances, when this course has been pursued, in which the secondarily affected glands have recovered before the disappearance of the primary affection, pointing, I think, to the probability that the irritant has been passed on to these through the lymphatic channels.

At present I am trying the effect of freezing the cancerous nodules in two cases of recurrent disease, and in one of primary disease in the breast, combining this, however, with dietetic, hygienic, and therapeutic measures, and with every evidence of successful results.

The strength of the infusion of capsicum I would recommend to commence with is 1 ounce of pods, broken up and infused in a pint of boiling water, and decanted in two hours.

It will be found, in the use of this application, that after a few days a crust will have formed which will separate in a short time, when the condition of the raw surface will indicate if a further application of the treatment is advisable. In any case it can do no harm. I have not had the courage so far to inject this infusion into a scirrhus tumor, but I see no reason why such a course should not be adopted, as the injection would be nontoxic to the normal cellular tissue, and could act only as a stimulant—and a highly diluted one at that—should it gain entrance to the circulation.

With regard to the freezing process which I have mentioned, I may state that in 1900 I tried this, in conjunction with the administration of a thyroid preparation and the usual dietetic and hygienic measures, in a primary cancer of the left mamma, which completely recovered; and it was the fact of my receiving a letter from my old patient a few weeks ago saying she was perfectly well, having not only regained, but retained her loss in weight, that emboldened me to have recourse to freezing again. My method consists in spraying the part with chloride of ethyl until complete coagulation takes place, and repeating this as soon as the part has recovered its natural color. Of course, it is desirable not to produce frost bite, but it will be found that the morbid cell will be destroyed long before that which is normal will lose its recuperative power.

I may be permitted to add that I have employed every device I could think of with a view to setting up an inflammatory action in cancerous tissue, but with no effect in this direction.

15 Half Moon Street, Mayfair, W.

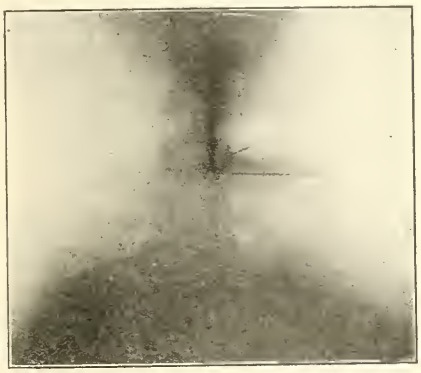
PERFORATING GUNSHOT WOUNDS OF THE PLEURA AND LUNG.*

By HENRY ROTH, M.D.,
NEW YORK.
ATTENDING SURGEON, LEBANON HOSPITAL.

Perforating gunshot wounds of the pleura and lung are of comparatively common occurrence, and, according to Rodman,[1] are ten times as frequent as gunshot wounds of the abdomen. Barthelemé,[2] in a study of the stab and gunshot wounds, which occurred in the surgical division of the University of Strassburg, from 1894 to 1904, found 76 severe stab wounds and 23 gunshot wounds of the chest. Borséky[3] reported 80 penetrating gunshot wounds of the chest which were treated in the surgical clinic of Budapest. Halter[4] reported all the gunshot wounds under treatment in Kocher's Clinic in Berne. Of 122 gunshot wounds, 19 were injuries of the pleura and lung; in 18 the injury was at close range. Fleischhut[5] based his thesis upon the penetrating gunshot wounds of civil practice, which were treated in the Berlin Charité from 1896 to 1905. There were 40 patients; in most of the cases the injury resulted from attempts at suicide.

During the past year we had under observation several patients with perforating gunshot wounds of the pleura and lung, and the following histories of cases will serve to illustrate the forthcoming remarks:

Case I.—Miss Elizabeth K., aged twenty-one years, native of the United States, was admitted to Lebanon Hospital on July 17, 1906. Family and previous history have no bearing upon her recent condition. About noon of the day of admission she received two wounds from a .32-caliber revolver, fired at close range. One bullet entered the third intercostal space about 2½ inches to the left of the



sternum, and was found underneath the skin of the posterior chest wall, near the inner margin of the scapula. There was a second wound of entrance, almost in the median line of her back, and on a level with the third lumbar vertebra. Bleeding from the wounds was very slight. Emphysema was present on her neck, left shoulder, and axilla. She was very restless, coughed constantly, and expectorated considerable blood. She was very pale, her respirations were labored, and the pulse was feeble and 136 to the minute. She complained of pain in her back, but had no symptoms to suggest penetration of the abdomen or spinal cord, there being no abdominal pain or rigidity, and no paralysis. There was no vomiting and the urine was normal. The wound areas were thoroughly cleansed and covered with sterile gauze, held in position by adhesive plaster and a binder. Codeine was given every four hours, and likewise saline solution per rectum, as her condition demanded it. Physical examination on the following day revealed all the signs of a hemopneumothorax on the left side, the flatness extending up to the angle of the scapula. She continued restless and coughed the rest of the day and the following night. Her temperature on July 17, 1906, was 101.2° F., pulse 120, and respiration 40. The bullet

*Read before the Society of Alumni of Lebanon Hospital, April 2, 1907.

from the chest wound was removed under cocaine anesthesia, and the patient was carefully watched to observe the first appearance of abdominal or spinal-cord symptoms. Cough and hemoptysis continued up to July 22, 1906. On this day, the sixth after the injury, the temperature and pulse were normal, respiration only slightly accelerated and the physical signs very much less marked. She was out of bed on July 30, 1906, and left the hospital cured on August 5, 1906. The accompanying radiograph shows the bullet about ¾ of an inch below the level of the scar, about ¼ of an inch to the right of the median line and between the spinous process and inferior articular processes of the third lumbar vertebra.

Case II.—Miss Lilian M., aged seventeen years, was admitted to the Lebanon Hospital on January 22, 1906. Fifteen minutes before admission she received a wound from a .32-caliber revolver which was aimed at the front of her chest, and was fired at close range. There was a small round wound above the third rib in the right mammary line. The bullet was found under the skin on the posterior chest wall, having perforated the chest in a straight line perpendicular to the anterior wall. The patient was in severe shock and had a very troublesome cough with hemoptysis. Pain was not complained of except in the back corresponding to the location of the bullet. The face was pale and had an anxious expression, and the lips were slightly cyanosed. The skin was cool and covered with cold perspiration. The pulse was feeble and rapid, and respiration was accelerated, short, and labored. Bleeding from the wound was very slight. The wound was thoroughly cleansed, the bullet removed, a dry dressing applied and held in place with strips of adhesive plaster and a tight bandage. She was put to bed with the head raised, morphine was given hypodermically and saline solution per rectum and subcutaneously. Reaction from the shock was prompt, the quality of the pulse improved, and the general appearance was better. The dyspnea and cough while still present, were more tolerable. On the following day physical examination revealed all the signs of hemopneumothorax of the right half of the chest. While all the symptoms improved rapidly, the pleural exudate remained stationary, and while it did not cause marked disturbances, it was deemed best after about three weeks to aspirate so as to relieve the lung of pressure and hasten absorption. This time there was a slight rise in the temperature, but aspiration revealed only dark fluid blood. Aspiration was repeated three times. Finally, about the middle of March, the temperature ran a higher course, there was a corresponding increase in the pulse rate, increasing emaciation occurred, and on exploratory puncture an empyema was found. On March 23, 1906, resection of portion of the seventh rib was performed. Drainage of the pleura was followed by rapid recovery, and the patient was discharged cured on April 18, 1906. She informed me recently that since leaving the hospital, she had gained 30 pounds in weight and is in excellent health. Whether the infection of the hemothorax dated from the time of the injury or was the result of the last aspiration, is not certain, but I am inclined to favor the latter possibility, although it was done under aseptic conditions.

Perforating gunshot wounds of the pleura and lung in civil practice are the result of attempts at suicide or homicide. Most of these injuries are caused by small-caliber weapons, being aimed directly at the chest, at close range. Bullets which penetrate below the sixth intercostal space usually perforate the diaphragm and cause injury of the abdominal viscera, such as the liver, spleen, stomach, and intestine. Such injuries as well as those in which the heart and large vessels are involved, will not be considered in this communication. The bullet usually penetrates the anterior chest wall and travels directly backward; it may enter in an oblique direction or pass from side to side. Occasionally it may run in a longitudinal direction or the wound of entrance may be in the neck or shoulder. The bullet generally traverses the lung and penetrates the opposite wall of the chest, but rarely passes out of the body, and is found underneath the skin. It might traverse both lungs, but may remain in the lung, or lodge in one of the vertebræ or ribs. If it perforates one of the ribs, spicules of bone will be driven into the lung, adding to the gravity of the injury. The wound of entrance is round and smooth, with slight inversion of the edges, and the skin surrounding it is discolored black, if the weapon is fired at close range. The wound of exit, if present, is like a slit or tear with everted edges, or may be large and irregular, if fragments of bone are driven through or the bullet is deformed. The bullet track is small and smooth and frequently hard to find. It generally remains sterile.

Perforation of the pleura permits the entrance of air and the development of a pneumothorax. Air may enter through the external wound or from the injured lung. The extent of pneumothorax will depend upon the size of the wound, which is usually small in the injuries under consideration. If a large bronchus is opened a very extensive pneumothorax will develop. If pleuritic adhesions are present, pneumothorax as well as hemothorax will be absent. The air from a pneumothorax is rapidly absorbed without any reaction, providing the lung is not extensively injured. Air from the lung may enter the cellular tissues and emphysema may develop which is usually circumscribed, but may become general. In gunshot wounds it is not so marked as in stab wounds.

Most gunshot wounds of the pleura and lung are associated with bleeding which may come from the lung, the internal mammary, or intercostal arteries. The escape of blood into the pleura causes a hemothorax which may be very slight, but may become so extensive as to threaten life from anemia and asphyxia. The accumulation of air and blood compresses the lung and acts as a hemostatic, if the bleeding is from the smaller vessels of the lung. The bronchi fill up with clots, but the blood in the pleura may remain fluid for a long time on account of the similarity between the pleural surface and the lining membrane of the blood-vessels. It is usually quickly absorbed and but rarely becomes infected, if not meddled with. In gunshot wounds prolapse of the lung is very rare. It usually involves the edge of the lung and, if not replaced promptly, may become necrotic.

Symptoms and Diagnosis.—Shock varies in its intensity, but is not always in proportion to the extent of the injury. Many patients fall, while others continue to walk for some distance. At times the patient falls unconscious, and where the heart and large vessels are injured, death soon occurs. The patient is usually pale, has an anxious facial expression, and the lips are livid. The body is covered with cold perspiration; the extremities are cool and the voice is feeble. The pulse is small, irregular, and may be imperceptible. Respiration is shallow, short and frequent, and dyspnea is rarely wanting. There is a very harassing cough, accompanied by hemoptysis which may be slight or profuse and may

last only a few minutes or continue for several days. It is one of the most constant symptoms of lung injury, but it may be absent. Pain varies in its intensity and location, and may be referred to the abdomen. There is more or less bleeding and blood may escape from the wound in large quantities, especially if the wound does not quickly close. When bleeding is very profuse, it is usually from the injured lung or from an injured intercostal artery. The location of the wound may throw some light upon the source of the blood, particularly if the internal mammary artery is injured. Dyspnea, at times, is very alarming. It is due to an extensive hemothorax or hemopneumothorax, and only rarely to a pneumothorax alone, which latter is readily recognized by a tympanitic area of varying extent. The pneumothorax as well as hemothorax may be double, and if not promptly relieved, may prove fatal; on the right side it is more dangerous than on the left. Dyspnea may increase or may develop some time after the injury, as the result of increased intrathoracic pressure caused by continued or renewed bleeding. The physical signs of hemothorax and hemopneumothorax are well known and need no repetition.

There may be one or more wounds of entrance; if there is no wound of exit, the bullet will frequently be felt underneath the skin of the opposite chest wall. Its location is often determined by the pain which it causes, but if not found soon after the injury it may be discovered later, on account of the ecchymosis which develops around it. Emphysema is usually present around the wound, but is not so extensive as with stab wounds. With small-caliber wounds there may be very few symptoms, nevertheless the diagnosis is not difficult, as a rule, and should be made without the use of the probe or fingers. Hemoptysis, hemothorax, hemopneumothorax, and emphysema are the most constant signs, but the lung may be penetrated without the presence of any one of them.

Clinical Course and Prognosis.—Perforating gunshot wounds of the pleura and lung, caused by small-caliber projectiles, are comparatively benign injuries. As Rodman[1] says: "They either die at once from shock and hemorrhage or very generally get well." Oliver,[6] in discussing Rodman's paper, made the following statements: "Gunshot wounds of the chest are, when properly treated, followed by a very slight mortality. The general impression gathered from writings on this subject is that these injuries are of a very serious and often fatal nature. This impression is, according to my observation and experience, entirely erroneous. If patients do not die within the first twelve hours from shock or hemorrhage, the vast majority will recover without serious illness, provided rest is given to the injured parts." This is in accord with the experience of military surgeons and Küttner,[7] from his large experience during the Boer war, speaks with authority when he says: "Gunshot wounds of the lung caused by small-caliber projectiles, in civil as well as in military practice, belong to the most favorable injuries, providing that the injured receive prompt and proper treatment." Hemorrhage from large vessels of the hilus are quickly fatal.

Of the 15 patients from Kocher's clinic (Halter[4]) only 1 died; the others recovered in a very short time; 13 of these presented pneumo- or hemothorax and 3 became infected. Of 86 patients reported by Borszéky[3] 11 died; 3 of these were moribund when received, 5 died of hemorrhage, and 3 from sepsis. Of the 75 who recovered, only 4 had complications, such as pneumonia, pyothorax, and gangrene of the skin. There was but one death in the 38 Strassburg cases. In the Berlin Charité (Fleischhut[5]) only 8 died of 40 patients; 28 recovered rapidly, and the others had to be operated upon for complications.

Hemothorax, if very extensive, may cause death, if not relieved by proper treatment. It may persist for some time, but if due to continuous, renewed, or late bleeding, may cause death as the result of anemia or asphyxia. In the class of injuries under consideration, the bullet rarely lodges in the lung, and therefore has no prognostic significance. Should a projectile lodge in the lung, it may become the source of later trouble. The most dangerous foreign bodies are pieces of clothing, but they are rarely encountered. The patients who recover from the immediate effects of the injury are apt to die later from sepsis, but with small caliber projectiles this is comparatively rare, and, if present, can readily be dealt with. It is usually due to meddlesome surgery (Rodman). Pneumonia, abscess or gangrene of the lung, and pyemia, are mentioned as possible causes of death.

Treatment.—Conservative treatment is the best prophylactic against sepsis and is the *sine qua non* of success. Only the exceptional cases require active interference, and to quote Rodman again:[1] "The treatment of shot wounds of the thorax should, as a rule, be a masterly inactivity. The less done the better." Senn writes:[8] "From what has been said, it is clear that the best treatment in penetrating wounds of the chest consists in hermetically sealing the wound of entrance and exit, if the latter exists, under strict aseptic precautions, immobilization of the chest by bandaging and rest, and in watching for and treating subsequent complications as they arise."

Care of the wound of entrance and exit, and the treatment of the primary symptoms, will demand immediate attention. Transportation should be avoided, but if unavoidable it should be done quickly and with the utmost care. Examination with a probe or finger has been the cause of many mishaps; it is useless and should be scrupulously avoided. If bleeding is not profuse, the external wound and surrounding area should be thoroughly cleansed, under the strictest aseptic precautions, and protected with a sterile gauze dressing, held in position by strips of adhesive plaster. The patient should then be turned on his side, to locate the wound of exit; this, when present, should be dealt with similarly to the wound of entrance. Should the bullet be felt under the skin, it may be removed at once or at some later time; but search for it, unless it is within easy reach, is to be avoided. The chest should be immobilized with a tight bandage, adhesive plaster, or plaster-of-paris. The patient should be placed on his back, with the head raised, and absolute rest, both physical and mental, provided for. A hypodermic injection of morphine will relieve the distressing cough and allay fear and anxiety. If the patient is very much prostrated, saline enemata or hypodermoclysis will prove of great benefit. Oxygen may be of value in alleviating dyspnea. Ordinarily, nothing more is necessary. The patient reacts from the shock, the dyspnea and cough subside, and recovery takes place without any complications. This may occur even where the primary symptoms are very alarming, and it is best not to be in too great haste to interfere. As it is very difficult in the beginning to judge of the gravity of the injury, constant and careful observation is very important.

Immediate surgical interference may be de-

manded by very profuse external or internal bleeding and the resulting anemia and asphyxia. In gunshot wounds external bleeding is rarely marked, but if present, it may be continuous or intermittent. It may be caused by injury of an intercostal artery, which may necessitate exploration of the wound, followed by ligature or tamponing. The bleeding point may be ligated by dividing and separating the periosteum from the lower and inner surface of the rib and passing a ligature on a curved needle around the artery, as suggested by Lejars. At times, resection of the overlying rib may be necessary. Injury of the internal mammary artery will demand double ligation, above and below the wound. This will require a horizontal incision between the costal cartilages, about a finger's breadth from the sternal margin. If the hemorrhage is from the large vessels of the lung the patient will die before active measures can be adopted. Where hemorrhage is very alarming, but not rapidly fatal, thoracotomy may be necessary. This operation is advocated mainly by French and Italian surgeons, and is a very desperate step, but will at times save patients who would otherwise die. There are several cases on record where this operation was done with success. Garré[9] advocates thoracotomy and primary suture of the lung in abundant hemorrhage into the pleura in long-persisting or repeated hemorrhage, and in pneumothorax if not relieved by puncture. If the wound is near the hilus, only tamponing is feasible. He finds that a very large wound is necessary—large enough to admit the introduction of the hand. For suture material he prefers silk and advocates drainage. Thoracotomy may necessitate resection of several ribs or a large flap, containing all the structures of the chest wall, may have to be reflected. The blood must be evacuated, the wound found, and the bleeding checked by suture, ligature, or tampon, all of which is very difficult. Dawbarn[10] advocates cording of the limbs close to the trunk, three limbs at a time, thereby accumulating blood in them until, from partial anemia elsewhere, faintness follows; whereon, as a result of weak heart action, there is opportunity for clotting. Puncture and aspiration will relieve intrathoracic pressure, but may cause renewed bleeding. If done at all, it should not be done too early, and only a small quantity should be removed at a time.

Hernia of the lung, if present and recent, should be replaced at once. When of longer duration, it may be ligated, resected, and cauterized, or left to slough off if gangrenous. Emphysema rarely requires any treatment; if very extreme it may necessitate multiple incisions. If the pneumothorax causes alarming symptoms, puncture and aspiration will afford prompt relief. After the primary symptoms have subsided there may be a sudden or gradual change, which may demand surgical interference. If the exudate increases it may require aspiration, or even thoracotomy. The mere presence of a rise in the temperature with a hemothorax is no indication for operative interference. Should an empyema develop, thoracotomy with or without resection of the rib, will be necessary.

THE MODERN THERAPY OF CYSTITIS.*

By MARTIN W. WARE, M.D.,

NEW YORK.

ADJUNCT SURGEON, GENITO-URINARY DEPARTMENT, MT. SINAI HOSPITAL.

A few prefatory words as to our conception of cystitis to-day will materially aid in the understanding of the therapeutic means at our disposal to combat this illness.

Cystitis—inflammation of the bladder—is due to bacterial invasion of the bladder wall. Most frequently the organisms are conveyed from without, in consequence of the introduction of nonsterilized instruments, and a further disregard of the principles of asepsis and antisepsis so devoutly followed when instruments are employed in other surgical manipulations. Bacteria may invade the bladder from the adjoining viscera (rectum, vagina) which they normally inhabit. Either of the aforesaid modes of infection of the bladder is favored by any such pathological conditions of the bladder and urethra which bring about retention, thereby affording the bacteria a chance to multiply in the retained urine. If now a traumatism of the bladder (catheterism) be added we have a third potent factor responsible for the cystitis. Infection of the bladder by extension from the diseased kidney and ureter mostly concern us in tuberculosis, and this descending infection is the rule, save where there is direct extension from the tuberculous vesicles and prostate.

Rarely is bacterial invasion of the bladder conveyed by the blood stream. The most commonly encountered organism is *Bacillus coli communis*. Staphylococci and streptococci may initiate and predominate in the acute forms of cystitis, but they are soon outgrown by the colon bacillus. Other organisms are occasionally found, such as *Proteus vulgaris* and *Bacillus pyocyaneus*. Earlier investigators laid much stress on the distinctions of cystitides with alkaline or acid urines. It is now admitted that the alkaline decomposition of the urine is not the peculiarity of any one organism.

Cystitis, while it is a pathological entity, is not so clinically. It is always a concomitant of some other pathological condition. Our therapeutic efforts, while on the one hand specifically directed against the infecting organism of cystitis, on the other hand must aim to remove the obstructing cause of cystitis, *e.g.* stricture, calculus, new growth, prostatic enlargement. To this extent only can we systematize our therapy.

The onset of the greater number of cystitides dates back to the first introduction of the catheter (infected?) or some other urethral instrument. With all the unpreparedness peculiar to haste, the dire consequences of infection must needs follow. A consideration of the measures preventive of infection are, therefore, first in order.

Prophylaxis.—Urinary retention from its manifold causes, when it has to be relieved by catheterization, should never be hastily done. It is, in no sense, so great an emergency procedure as to warrant any

*Read before the Williamsburgh Medical Society of Brooklyn, N. Y., May 13, 1907.

violation of antisepsis and asepsis. Aseptic catheterization is thus performed. The glans penis is cleansed with soap and water, followed by a washing with bichloride of mercury, 1-2000. The anterior urethra is rendered as clean as possible by a few irrigations with boiled water or 3 per cent. boric acid, which may be performed with a small glass urethral syringe previously sterilized in boiling water.

The surgeon's hands are to be as carefully prepared as for any operation before taking hold of the sterilized catheter. A refinement to safeguard against infection is the recommendation to grasp the catheter with a sterilized anatomical forceps, and therewith guide the sterilized catheter along the urethra into the bladder. Thus all manual contact is avoided. The lubricant for the catheter and instruments should be some sterile medium—nowadays purchasable as a jelly, made of Irish moss impregnated with essential oils, or some antiseptic. In the absence of this, olive oil, sterilized by boiling, will answer. Instead of lubricating the catheter, the urethral canal should be distended with the lubricant. It is not possible here to enter upon the methods of sterilizing the varieties of catheters, but the soft rubber catheter, which should always be the first instrument to be drawn upon in catheterizing, can readily be sterilized in boiling water. When retention exists or is expected, or when catheterization may be anticipated, it is expedient to administer a urinary antiseptic in advance, to prevent bacterial growth in the urine and invasion of the bladder by the organisms. Finally, after the bladder is emptied, a 4 per cent. solution of boric acid or, better, 1/1,000 solution of nitrate of silver should be introduced and an ounce left in to be voided by the patient.

These precautions obtain with equal force in the event of any other instrumental examination. The surgeon avails himself of innumerable safeguards before aspirating a knee-joint, and yet it is only at this late day that he is becoming keenly alive to the necessity of as much vigilance in catheterizing a distended bladder.

Acute Cystitis.—When once the bladder is infected—with its train of symptoms, frequent and painful micturition of a turbid urine, with vesical tenesmus—it should be the first duty to enjoin rest in bed, and, though cloudy the urine may be, no attempt to irrigate the bladder is in place, for the distention of the bladder will provoke more pain and spasm. The bladder, too, needs rest. This may be obtained by the use of suppositories of opium or codeine and hyoscyamus at frequent intervals. Hot, moist applications to the suprapubic region and hot sitz-baths, when these are available, greatly allay the vesical spasms. Hand in hand with these measures, urotropin in 0.5 doses should be administered from the start, to retard the growth of the organisms that have infected the bladder. It is no longer our practice to rely on the doubtful sedative action of copious draughts of decoctions of triticum repens, or uva ursi, or buchu.

The use of liberal quantities of water is an advantage insofar as it dilutes an irritating infected urine; its disadvantage consists in the frequent urinations that it provokes. An infected urine, whether alkaline or acid, will provoke a pain in equal degree; it is therefore of lesser importance to prescribe alkalies to diminish the acidity, or to order benzoic acid to increase the acidity, than to reduce the degree of infection by urinary antiseptics. When the acuity of symptoms has diminished, local treatment of the infected region may be commenced. This does not imply irrigation by catheter with fluids of any volume, but rather an instillation of a few drops of a solution of nitrate of silver, ½ to 5 per cent., into the neck of the bladder. Such instillations are to be made with a Guyon catheter, of small caliber. To its outer, funnel-shaped end is attached a small hypodermic syringe, containing the silver nitrate; the solution is to be slowly delivered. The immediate effect is very painful, but opiates allay this. Within 24 to 48 hours improvement will follow, and after the second or third day another injection may be given, increasing the strength of the silver. As the bladder becomes more tolerant we may resort to larger washings of the bladder with boric acid, 4 per cent., and silver nitrate, 1-4,000 to 1-1,000. The acute urethrocystitis (*Cystitis colli vesicæ*) of gonorrhea is the type of acute cystitis most commonly encountered, and the treatment of which we herein refer to. The clinical picture is decided enough to preclude any cystoscopic examination.

The summary of the treatment of acute cystitis resolves itself into: Rest in bed; rest of the bladder, with opiates; abstinence of all instrumentation; urotropin by mouth; later on, topical applications, and, finally, free irrigation of the bladder.

Chronic Cystitis.—The acute cystitis will persist as a chronic cystitis in the presence of any obstruction to the urinary outflow, such as strictures, calculi, prostatic hypertrophy, and new growths.

The stricture should be dilated to relieve stagnation of the urine, and with the gradual restoration of the canal to its normal caliber the urine will become clearer and the vesical symptoms abate. If a catheter of fair caliber can be introduced, the bladder should be cleansed with copious washings of a warm 4 per cent. boric acid solution, temperature 108° F., followed by an irrigation of warm silver nitrate, 1-4,000 to 1-1,000. Inasmuch as very tight strictures should not be dilated oftener than every third day, the irrigations, under these circumstances, should likewise be thus limited; otherwise, daily irrigations are in place, and, if an attack of retention complicate the stricture, which proves to be impermeable to instruments, a suprapubic puncture with a fine aspirating needle should be performed once or twice, in the hope of entering the bladder by the natural route later on.

The indication for perineal section to drain an infected bladder is imperative only if sepsis exist, or if the stricture does not yield to dilatation. The perineal drain, however, need not be allowed to remain *in situ* more than 48 to 96 hours. At the expiration of that time it may be removed, and daily or bi-daily irrigations of boric acid and silver in sequence, 100 c.c. to 150 c.c., according to the bladder capacity, are to be performed by way of the perineum and the urethra later on. The irrigations should be warm, and the volume injected adapted to the capacity of the bladder.

In the cystitis peculiar to vesical calculi, we have to contend with a bladder spastic in its efforts to rid itself of its stone, and contracted by virtue of the long-standing inflammation of its infected walls. Any attempts to cure the cystitis by irrigation will fail until the stone is removed, preferably by crushing, if its size and consistency warrant it or by suprapubic section. Aspiration of the crushed fragments is more effective if the bladder is distensible and will accommodate fluids. To this end our efforts should be directed to allay the acute bladder symptoms by rest in bed for some days before the operation, and by gentle irrigations with boric acid and silver to combat the infection. With the removal of the stone, the bladder capacity may be enlarged by daily

forcible distentions with warm boric acid solutions (4 per cent.).

The cystitis associated with prostatic hypertrophy originates with the catheterization for the withdrawal of residual urine or retention. Prophylactic measures, already referred to, will avert it, and when patients nowadays resort to catheter life, a schooling of the patient in the most painstaking asepsis is necessary.

Atonic bladders, harboring large quantities of infected residual urine, tend to keep up the cystitis. Rather than resort to frequent and difficult introduction of the catheter, an indwelling catheter will do away with residual urine, and by avoiding distention of the bladder may restore its tone.

An indwelling catheter may be of the soft rubber variety or an elbowed woven instrument. The eye of the catheter should just protrude beyond the internal urethral orifice. If more of the catheter lies within the bladder it will, like any other foreign body, provoke spasms, and, the bladder becoming intolerant, it is likely to be rejected. To prevent the catheter from being displaced into the bladder or expelled, it should be fastened with adhesive plaster to the penis. Special types of catheter with shoulders (Pezzer and Malecot) prevent the expulsion, but do not provide against further entrance of the instrument into the bladder. The outer end of the catheter may be corked and the urine drawn at stated intervals, or the urine may be continuously syphoned into a vessel alongside of the bed. Irrigations may be performed through the catheter. In the presence of an obstructing prostate, the chance of curing a cystitis is *nil*. The favorable influence of repeated catheterization or permanent catheterization is its effect in reducing back pressure upon the kidneys. This is of much value preliminary to contemplated prostatectomy. A disadvantage of the catheter *à demeure*, difficult to avoid, is the infection of the urethral canal, which, in turn, causes epididymitis. In cases of acute retention, the catheter *à demeure* may be instrumental in restoring tone, but, in chronic retention, it is a temporary expedient. Where prostatectomy is certain to follow, the back-pressure of the kidneys may better be relieved by a preliminary suprapubic opening of the bladder, with drainage and irrigation of the viscus for a week or more preliminary to the removal of the prostate. The infected bladder may be subsequently treated effectively with irrigations of boric acid and silver nitrate.

Aside from the removal of the obstructive cause in the types of cystitis, just gone over, there are some undetermined forms of cystitis that are chronic. The cystoscopic examination may show a diverticulum, favorable to operation, or a communication with a pus cavity outside of the bladder, or parasites or central nerve lesions (spinal). And even after these forms are excluded, the chronic cystitis may be rebellious to all irrigations. These varieties soon become accustomed to the irrigating medium, and for this reason the fluids must often be changed, and with lapse of time return to the original one. We may try oxycyanide of mercury 1-3,000, permanganate of potassium 1-400, acetate of alumina 1-500. For the foul-smelling bladders of inoperable carcinoma, ½ of creolin or lysol, 1-5,000, is effective.

Bacterial examination of the bladder urine is of service from time to time, to show the reduction in the number of bacteria. If, after careful and most persistent irrigations, a chronic cystitis does not yield, a suprapubic opening into the bladder is indicated for the purpose of curetting and cleansing the bladder wall, and freely draining its cavity.

It has become an axiom that whenever a cystitis is rebellious and does not yield to silver nitrate irrigations, and, furthermore, does not tolerate these, we must become mindful lest we have to deal with tuberculous cystitis. If bacteriologically proven to be tuberculous, and the cystoscope can be introduced under general anesthesia, if necessary, when the bladder capacity is not below 60 c.c., the source of the tuberculosis may be traced in the overwhelming instances, to one kidney in the beginning of the disease. At this stage a nephrectomy of the diseased kidney, with removal of the ureter in some cases, will promptly be followed by a subsidence of all bladder ailments. Occasionally, the bladder is extensively invaded by the tuberculosis, or the renal lesion is bilateral, or adjacent sexual organs, more commonly in the male than female, spread the disease to the bladder. Under these adverse circumstances, one's ingenuity will be taxed to the utmost to alleviate the progressive aggravation of the vesical symptoms, which have so aptly been named "cystite-douloureuse" (Guyon).

Before the bladder is much contracted large irrigations may be used, but never to the point of distending the bladder to its full capacity. Of these, bichloride of mercury, 1-10,000 (Guyon), or boric acid, 3 per cent., followed by 3 per cent. phenol., at a temperature of 108° F., once or twice a week (Rovsing), have not, however, been successful in my hands. Silver nitrate, if at all used, should only be instilled in small quantities. When the tuberculous bladder has begun to contract, all irrigations are intolerable, and instillations alone may be borne; and even these are possible only if preceded by instillations of cocaine. Directly aimed at the tuberculous nature of the infection are injections of iodoform suspended in mucilage.

It has been suggested by Bazy to bathe the bladder permanently with iodoform by injecting a suspension of iodoform in olive oil or liquid vaselin into the bladder partly filled with boric acid solution. The oily mixture floats on the solution; the patient is then directed to void his bladder contents until the iodoform appears; he is then to cease, so that the iodoform bathes the bladder. This procedure is repeated at each subsequent micturition. Thus, the iodoform oil is retained.

Guaiacol, to the extent of 5 per cent., may be added to the mixture, and is valuable for its anesthetic effect. One-half an ounce to an ounce of the mixture may be tolerated, but sensitive, contracted bladders resent even this. In some cases, following the advice of Pasteau, instillation with a catheter and small syringe of a 25 per cent. or a 50 per cent. solution of guaiacol in olive oil will allay the irritability for hours. Of very recent date is the suggestion of Frank, to inject a suspension of calomel into the bladder, and administer *per os* iodide of potassium. The latter, being eliminated by the urine, converts calomel into iodide of mercury in so diluted a form as to be unirritating.

Where there are repeated hemorrhages to indicate the existence of an ulcerating surface, or if cystoscopy can possibly establish such a condition, the topical treatment of the ulcer is possible. In females, topical applications of silver nitrate, always under narcosis, have been effective.

As a last resort, the bladder may be opened to curette the ulcerations, remove fungating tuberculous masses and calcareous deposits. Rarely will the fistulous opening heal either because of the infection of the channel or from the urine laden with tubercle bacilli, and because of the contracted state of the bladder. In view of this fact, it has been

advocated to open the bladder in the female, in the vagina, and thus spare the patients the loathsome discomfort of an incessant flow of urine over the abdomen.

The limitations of surgery have been reached by this operation, and even with the relief afforded by the suprapubic fistula, the pains may be so excruciating that I see it recorded by Fenwick that pitting of the spinal cord low down was resorted to. Of internal remedies, urotopin is absolutely useless in tuberculous cystitis. Guaiacol carbonate, or guaiacol, in 5-grain doses and larger, long continued, coupled with hygienic and dietetic treatment, is of much service. Inoculations with bacterial vaccines has, in the hands of its originator, Wright, effected cures in tuberculous cystitis, and antedating this authority, Fenwick refers to benefit resulting from use of tuberculin in doses of 1/1,000 m.g., and recently excellent results are also reported by De Keersmacker. The best preventive of tuberculous cystitis is an early nephrectomy of the primary tuberculous kidney. Advanced tuberculous cystitis is a "noli me tangere."

1198 Lexington Avenue.

TUBERCULOSIS OF THE MIDDLE EAR.

By ALBERT BARDES, M.D.

NEW YORK.

ATTENDING SURGEON AT THE NEW AMSTERDAM EYE AND EAR HOSPITAL, AND ASSISTANT AT THE MANHATTAN EYE, EAR AND THROAT HOSPITAL.

Now that the causation of disease is becoming better known, we find that the subtile bacillus of tuberculosis is at the bottom of many conditions that were formerly thought to be nontuberculous. In the ear, for instance, a tuberculous infection was regarded as a very rare occurrence, and the disease one that invariably proved fatal. A better understanding of this affection, however, and the careful investigation of clinical data bearing upon the subject, show that it is of not infrequent occurrence, and that timely treatment is not only efficacious in most instances but frequently curative as well.

In former years tuberculosis of the middle ear was usually mistaken for a chronic suppuration of the ear, and as such it was treated, with very poor success. At the present time, however, we are, in most instances, able to differentiate between the two diseases, and consequently we obtain far better results than formerly, since upon the early recognition of the disease depends the issue of the case.

It is particularly in marasmic children—those with swollen glands, joint lesions, and chronic eruptions—that early treatment is of the greatest importance, in order to forestall the ravages of the disease, and to preserve the usefulness of the ear and the life of the patient.

It is estimated that in fully 65 per cent. of the vast army of children that have a running ear the trouble is of a tuberculous nature. Formerly these children were regarded as scrofulous, but as scrofula is no longer considered a separate disease, but simply a manifestation of tuberculosis in the child, the running ear in these children proves to be nothing more than a cold abscess.

It is surprising to see how extensive the destruction of bone can be without any visible external evidence. Very often the ossicles, the bony walls of the middle ear, and even portions of the internal ear, are destroyed before the parents are even aware that their child is suffering from a dangerous malady, and it often happens that the tuberculous focus in the ear is the starting point of a tuberculous meningitis, that is so common among young children, or perhaps of a general septic intoxication that reacts upon the system and causes a rapid decline in health.

In the clinics we often see children with neglected tuberculous lesions of the ear, where the destruction of bone has been very great, and where Nature has provided a fistulous opening behind the ear for the escape of the broken-down material. In this way the abscess cavity becomes circumscribed and the infection is prevented from entering the circulation and becoming general. When these children are operated upon the tuberculous nature of their affection soon becomes apparent. The wound takes on a sluggish and unhealthy appearance. There is a constant tendency to the formation of edematous granulations and fistulæ, and the wound refuses to heal until supportive and antituberculous treatment is given.

In children, a tuberculous ear trouble may manifest itself at any time, even when there is no noticeable involvement elsewhere, and the child is in apparent good health. In other words, in children there appears to be no direct connection between a process in the ear and one in the lungs. Among adults, however, tuberculosis of the ear usually accompanies or else follows a pulmonary lesion of the same nature, the ear trouble generally appearing during the later stages of the lung affection, and at a time when the system is enfeebled and the resisting power of the organism is diminished.

The manner in which the ear becomes infected in tuberculosis has given rise to much discussion, and various opinions have been advanced in regard to the path by which the tubercle bacillus effects an entrance into the middle ear. There are four ways in which this chamber can be approached: Through the eustachian tube; through the lymph channel; through the blood current, and through the external ear. Most observers are agreed that in nearly every instance the channel of infection is the eustachian tube and the infecting medium is the sputum.

In health, the middle ear is protected against disease by a number of safeguards, which prevent infectious matter from gaining entrance to it. Experimentation shows that the healthy middle ear is an aseptic chamber, and has the power of expelling such foreign material as may find its way into it. It appears that the epithelial lining of the tube and middle ear has a positive germifugal action, and by means of the outward movement of its cilia and mucous secretion it promptly expels into the nose any deleterious matter that may find its way into the middle ear. It has been proved that when the epithelial lining of the tubes and middle ear is intact, infection of the ear by way of the nose is impossible. As a further protection, the eustachian tube is closed, like the urethra, in the state of rest, and its nasal orifice is snugly sealed by a cushion of fat, which gives it the appearance of the end of a trumpet. By these means the main avenue of entrance to the ear is doubly guarded, and the multitude of pathogenic organisms that are constant inhabitants of the postnasal space are effectually excluded.

In a wasting disease like pulmonary tuberculosis, the demand for heat-producing material exceeds the natural supply of the animal economy, and consequently the surplus energy in the form of fat that is stored away in the cellular tissues of the body, is drawn upon to satisfy the increasing wants of the system. The pad of fat at the orifice of the eustachian tube is among the first to become absorbed, and at the same time the tube itself shares in the general phthisical atrophy, and it, too, be-

comes diseased. Under these circumstances it is easy to understand how an expiratory blast, such as occurs in coughing and blowing the nose, can force infected sputum into the middle ear, where the sluggish inflammatory action of the general tuberculous process has already weakened the resisting power of that organ and has prepared the way for the actual infection.

As said before, it is impossible to infect a healthy ear, but an ear that has already become enfeebled through some debilitating process, such as the tuberculous, furnishes a fertile field for pathogenic organisms, on account of its rich supply of lymphatics. As soon as the tubercle bacilli succeed in gaining a definite foothold in the middle ear, certain pathological changes take place, and these changes are constantly present in all tuberculous lesions, no matter where they are located. The first change consists in the deposit of a mass of cells, forming the well-known giant cell or miliary tubercle, which constitutes the first distinctive change in all tubercular processes. As the destruction goes on, these tubercles in turn become infiltrated and softened, and eventually they break down into an ulcerating mass, the resulting débris acting as a foreign body and seeking an exit from the ear. As long as the drum head remains intact and keeps the middle ear shut off from external influences the destruction proceeds slowly, but as soon as it becomes eroded and perforated, the middle ear becomes infected by pus cocci from without, and rapid disintegration ensues. The promontory of the middle ear is the point of predilection in tuberculosis of the ear, and then the disease extends to the ossicles, and spares neither the bony walls of the ear nor the adjacent bony parts. Fortunately for the hearing, the most indispensable of the ossicles, the stapes, resists destruction to the last, thanks to its excellent blood supply, which comes from the internal ear. If the destruction becomes active the labyrinth and the mastoid cells are gradually invaded, and a general septic intoxication is likely to follow unless the disease can be checked. This perhaps explains the insidious onset of facial paralysis and labyrinthine symptoms that occur in the course of certain seemingly mild infections of the middle ear. Excepting in children, intracranial complications are rare in this affection, owing to the facility with which the septic matter can usually escape from the ear.

At the same time that destruction is going on in the ear, the reparative phenomenon that accompanies all disintegrating changes is also in evidence. This is shown by the mass of granulations that are caused to be thrown out, in order to combat the infection and to protect the diseased area. The granulations that cover a tuberculous lesion, however, are pale and flabby, and are so unlike healthy ones that they fail to accomplish the purpose for which they were intended, and retard rather than facilitate the healing process. It is owing to the low vitality of the middle ear in tuberculosis that aural polyps and large granulations are seldom encountered, and it is for this reason that the retrogressive changes usually predominate over the reparative unless the diseased parts are stimulated.

It often happens that the nutrition of the system and the vitality of the ear can be improved to such an extent that the granulations take on a healthy action and permit the diseased area to heal. When this takes place the diseased part becomes covered with a firm layer of connective tissue which eventually cicatrizes. Frequently, while reparation is going on in one part of the ear, destruction is going on in another, so that the destructive process is being constantly offset by the restorative. In this way a tuberculous ear trouble may last for years without changing perceptibly. In the multiple perforations in the drumhead of a tuberculous ear we have distinct evidences of the attempts of the reparative process to heal the breach and close the middle ear, and with assistance the attempts are often successful.

Nearly all observers are agreed that tuberculosis of the middle ear never occurs as a primary infection, and that the channel of infection is never through a hole in the drumhead. This may appear paradoxical when we consider the wide distribution of the tubercle bacillus and the many chances of infection, but when we bear in mind two important factors mentioned by Koch concerning the bacillus, namely, that it is an extremely slow growing organism and is one that requires for its wellbeing both a suitable soil and a quiet resting place, the matter seems clear. These requirements are hardly to be obtained in such an exposed place as the middle ear, where the mucous flow and the probability of a puscoccal infection from without would cause them to be eliminated before they had a chance to establish an infection.

It occasionally happens that a tuberculous affection of the ear occurs quite independently of a pulmonary lesion, and at a time when the health appears to be good. When this takes place we are led to assume that the ear became infected at an earlier period and at a time when the lungs were diseased. It is known that tubercle bacilli have remained encapsulated in a bronchial gland for years without losing their vitality, and there is every reason to believe that the same thing can take place in the ear. That the tubercle bacillus is almost indestructible is shown by the fact that under proper conditions this organism can retain its vitality for upwards of twenty years.

It is very seldom that a case of tuberculosis of the middle ear comes under observation in the early stage of the disease, or before the ear has begun to discharge. This is mainly because the disease at first presents no more alarming symptoms than impaired hearing and a sense of fulness in the ear, symptoms that are usually disregarded. Occasionally we see an ear in which there is a beginning tuberculous lesion, where the drumhead presents a soggy, lusterless appearance that is in harmony with the general tuberculous habit. Through it we can often see the yellow outlines of the tubercles that stud its inner surface and that of the middle ear. As soon as these tubercles break down the resulting débris causes an erosion of the drumhead, and in this way it escapes from the ear. This discharge is at first thin and watery and contains tubercle bacilli in abundance; presently, however, the middle ear becomes infected by pyogenic organisms from without, and then the discharge becomes thick and purulent, and in every respect resembles that of a chronic purulent otitis. This is the time when most patients first come for treatment, and unless all of the characteristic features of the disease are considered, we are apt to be misled as to its real nature.

In adults, tuberculous disease of the ear presents certain clinical features which are distinctive of this affection and are present in no other. When a person in failing health, or with the history of a previous pulmonary trouble, complains of persistent deafness and a discharge from the ear that began without ache or pain, we can at once suspect tuberculosis, particularly if the patient has a cachectic appearance and the mastoid or the cervical glands

are enlarged. Almost invariably, when an ear that is nontuberculous is about to discharge, the pain is most intense, the temperature is elevated, and there are other signs of an active inflammation.

In tuberculosis the appearance of the drumhead is particularly characteristic. It is of a dull, cheesy color, and usually contains numerous perforations, and these have everted and thickened edges, which give to the drumhead the suggestion of a tuberculous lesion. In certain cases the entire drumhead melts away through a process of liquefaction necrosis, and the bare bone can be felt and sometimes seen beneath the ulcerated surface of the middle ear. These bony lesions of tuberculosis are noted for their insensitiveness to pain when touched with the probe, and even when they are scraped, and also for their anemic and noninflammatory appearance.

A positive diagnosis of tuberculosis of the middle ear can be made only by finding the tubercle bacilli in the aural discharge, or better still in the granulation tissue of the middle ear. As before stated, it is difficult to find the tubercle bacilli in a well-established aural discharge for the reason that a pyogenic infection usually becomes engrafted upon a tuberculous, and the organisms of the former process multiply with such rapidity that they soon predominate over the tuberculous to such an extent that the finding of the tubercle bacilli becomes a matter of uncertainty and difficulty. The tubercle bacilli are more apt to be found in the residual discharge of the middle ear than in that which escapes from the ear. Whenever the germs cannot be demonstrated in the discharge or in the tissues of a suspected tuberculous ear, the débris should be injected into the peritoneal cavity of a guinea-pig, and if tubercle bacilli are present the animal soon develops tuberculous peritonitis.

The treatment of tuberculous affections of the middle ear is that of the disease in general, and is both prophylactic and active. Our first aim should be to check the progress of the disease and to acquaint the patient with the infectious nature of the aural discharge, that it may be destroyed before it can infect others. Of course the discharge is not nearly as infectious as the sputum, but nevertheless it should be treated in the same way.

In most instances the aural affection is but a part of the general tuberculous involvement and calls for the observance of the laws of hygiene and of the application of such general surgical principles as occasion demands. In many instances the patient is not seen until the tuberculous process is far advanced and the health is rapidly declining. In such a case little can be done save to attempt to stem the ravages of the disease and build up the general health. Seen in the early stage, and before the destruction is well under way, a great deal can be accomplished by removing as much as possible of the diseased tissue and encouraging the sluggish granulations to a healthy reaction. We must bear in mind that we are dealing with a cold abscess, and we should adopt the same rules that apply to the treatment of tuberculous abscesses in general. Free drainage is essential, and to secure it it may be necessary to convert the small perforations into one large opening. By this procedure the diseased area can be stimulated and often made to heal by the application of a 5 per cent. solution of lactic acid or a 10 per cent. solution of chromic acid. In stubborn cases the curette should be used to remove the softened mass of tuberculous tissue, and then the part should be dusted with iodoform. Irrigations should be employed as sparingly as possible, a solution of lysol 1-200 being the best. Of course, it is understood that the nose and throat must be kept clean with alkaline sprays, in order to prevent reinfection through that channel, and the ear should be inflated occasionally in order to keep the tubes and the middle ear clear.

If there are symptoms of mastoid involvement the cells should be laid open and the diseased bone should be thoroughly removed. It is particularly in children that this radical procedure is of the greatest benefit in bringing about a cure and at the same time saving the hearing.

In connection with local treatment it is understood that the general health should be improved as much as possible and the patient given the benefit of such measures as are known to counteract the general tuberculous process. In the event that these fail to arrest the progress of the disease it is advisable to send the sufferer to the mountains, the dry air of which often has a favorable influence upon tuberculosis of the ear in particular.

THE DIFFERENTIAL DIAGNOSIS BETWEEN CHOREA MINOR AND TIC.*

By WILLIAM W. GRAVES, M.D.,

ST. LOUIS, MO.

The time was, even in the recent past, when the term "chorea" was applied to several conditions which to-day may be readily differentiated from each other. It is one of the triumphs of modern neurologists to have successfully differentiated chorea minor from other conditions resembling it. The condition formerly called "habit chorea," "habit spasm," "myospasia impulsiva," or "Gilles de la Tourette's disease," but more recently classed under the euphonious (?) name "tic," has in certain particulars, on superficial examination, a striking resemblance to chorea minor. Gilles de la Tourette, Brissaud, S. Weir Mitchell, Oppenheim, Gowers, Patrick, and Meige and Feindel, especially the last named authors, have so clearly described tic conditions that their differentiation from chorea minor should no longer be a difficult matter; yet this differentiation is not made as often as it should be made. Tic is a common and widespread disorder, almost, if not quite, as common as chorea minor, and since it was until recent years always called chorea, it is not to be wondered at that it is still frequently so diagnosed. But chorea minor is rarely called tic. In such a case no serious harm can ensue, because chorea minor, which is an acute, infectious, and self-limited disease, tends to spontaneous recovery, whereas the nature of tic is such that it tends to perpetuate itself; therefore the erroneous diagnosis, chorea minor, in a case of tic, may mean the promotion of invalidism. A correct diagnosis in chorea minor is not, but in tic is, absolutely essential to the patient's welfare. This fact alone was sufficient incentive for me to choose as a subject for this occasion the title of this paper. An additional incentive for bringing this subject to your attention is that I am constantly meeting in both clinic and consultation practice cases of tic of recent and long standing which have been erroneously diagnosed as chorea minor. I have recently had the gratifying experience of guiding to complete recovery a patient who had been a victim of tic for eleven years, and whose case had been repeatedly diagnosed and treated as chorea minor. The differential diagnosis between chorea minor and tic is not difficult—indeed it is a

*Read before the Missouri State Medical Association, May 15, 1907.

very easy problem—and requires for its solution no special training. It is one that any physician can readily make if he will only take time for observation. Some one has said, "More mistakes are made in diagnosis—many more—by not *looking* than by not *knowing*," and this saying finds justification in the differentiation between chorea minor and tic, since with no information other than that obtainable by "looking" the differentiation should be readily made.

That this subject may be succinctly placed before you for discussion, I have set down in parallel columns the salient points of contrast and resemblance which may guide one in the differentiation between chorea minor and tic.

CHOREA MINOR.	TIC.
1. General nutrition suffers early in chorea—the patient growing pale and anemic, and he shows early loss of weight.	1. Tic has no effect on general nutrition and this is usually good. Weight is not affected.
2. Expression, when face is quiet, is vacant, sullen and often stupid.	2. Expression is, as a rule, quick and vivacious.
3. Disposition is, as a rule, morose and depressed, but it is often characterized by great irritability.	3. Disposition is usually lively and is frequently childlike in tic.
4. Attention not necessarily but usually is somewhat diminished in chorea.	4. Attention is constantly diminished in tic.
5. A heart murmur is rarely absent throughout the course of the disease, and, unless previously present, is due to the choreic process.	5. A heart murmur, unless previously present, is never found in tic and it is never due to the tic process.
6. The respiratory function is often disturbed in chorea, the respiration becoming so unequal and irregular that a normal respiratory excursion rarely occurs and the expiratory phase is often *explosive*.	6. The respiratory function rarely shows disturbance in tic and never similar to that in chorea.
7. If the muscles of articulation are involved in chorea, speech is often indistinct, difficult, and momentarily impossible. Coprolalia and Echolalia are never present in chorea.	7. The muscles of articulation are never similarly involved in tic, and coprolalia and echolalia are often present.
8. Choreic movements are never confined to one part of the body throughout the course of the disease, though they usually *begin* in arm, face, or leg, and then rapidly extend to other parts; they may be one-sided in the beginning, but they usually become general.	8. Tic movements are usually confined to a single part of the body and they rarely become general.
9. Choreic movements are never confined to synergioly associated muscle groups; they are indefinite, vary in intensity, and frequently occur in individual muscles.	9. Tic movements are invariably confined to synergicly associated muscle groups; they are definite and occur repeatedly with varying intensity in the same muscle groups, but never in individual muscles.
10. Voluntary movements with the affected parts show a constant though variable degree of incoordination.	10. Voluntary movements in tic are never incoordinated.
11. Choreic movements are involuntary and these movements sow more or less incoordination.	11. Tic movements, as a rule, are not consciously but subconsciously voluntary, and they are never incoordinated.
12. Choreic movements are not lessened, but are usually made worse by any voluntary effort to control them	12. Tic movements are lessened and may be entirely controlled for a variable period of time by voluntary effort—the oftener the effort, the greater the control.
13. A choreic involuntary and incoordinate movement is a *purposeless* movement and was never *imitative*.	13. A tic movement in the beginning *was* either a *purposeful* or an *imitative* movement.
14. Any voluntary movement exaggerates the choreic movements.	14. Any voluntary movement usually lessens the tic movements.
15. Choreic movements are increased in emotional states.	15. Tic movements are usually lessened in emotional states.
16. Choreic movements are always exaggerated when the patient is in the presence of others and less when he is alone.	16. Tic movements are usually lessened when the patient is in the presence of others and aggravated when he is alone.
17. Marked associated movements are always present in chorea.	17. Marked associated movements are never present in tic.
18. Choreic movements are always unpleasant to the patient and are never accompanied by feelings of satisfaction.	18. When an inhibited tic movement gives way to the desire to tic, the ensuing tic movement is accompanied by feelings of satisfaction and pleasure to the patient.
19. In chorea minor frequently apparent but rarely actual weakness in certain muscle groups occur.	19. Neither apparent nor actual muscle weakness is ever due to tic.
20. Choreic movements cannot be imitated.	20. Tic movements may be readily imitated.
21. Chorea minor, with or without treatment, tends to complete recovery within from two to six months.	21. Tic, unrecognized and unaided, never tends to recovery, but naturally to perpetuate itself, and it may last a lifetime.
22. Chorea minor is a disease.	22. Tic is a habit.

232 VANOL BUILDING.

Renal Permeability in Hepatic Diseases.—Fiorenza Ignazio says that histological and biochemical researches have demonstrated the complex structure of the liver cells, as well as its complex functions. The culminating point in pathology refers to the changes in the liver cells in disease. There take place a series of complex biochemical changes related to combustion and dehydration, and from their study we can determine whether these cells are sufficient to perform their functions or no. Liver insufficiency would be characterized by failure in the biliary function and in the fat transformation, by alteration of the urogenetic function, and of the glycogenetic function. In order to study the effect on the urogenetic function, the author has experimented by administration of methylene blue in cases of organic disease of the liver, six patients being treated in all. Iodide of potassium and salicylate of soda were also administered. The author finds that it is impossible to establish a definite relation between the functioning of the kidney and of the liver in hepatic affections and their histopathology. The intermittent character of the appearance of the blue indicates that there is a special rhythm of secretion existing between the liver and kidney. The diseased liver acts in a special manner on the secretion of urine, permitting a more rapid elimination, and this is not due to the action of the kidney, but of the liver itself. The substance must pass through the liver first. Intermittent elimination of methylene blue reveals hepatic insufficiency. Hence this fact may be of use in diagnosis and prognosis. —*La Riforma Medica.*

Candy Factories Healthful.—A London physician has lately expressed the opinion that both candy and sealing-wax factories are very healthful places in which to work. The candy girls, he says, are allowed to eat as much sugar as they like, with an excellent effect upon their health. Experience shows that the sugar eater is proof against consumption, and it is impossible for her to become a drunkard. The resin dust in the sealing wax factories makes the air in them very stimulating, similar to that of a pine forest. It is true that the workers in these factories inevitably absorb with the dust particles of vermilion coloring, which is a virulent poison; but, according to the optimistic writer, even this has a good effect upon anemics.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, August 24, 1907.

ROENTGEN-RAY DIAGNOSIS OF POST-PNEUMONIC CONDITIONS.

CLEAR as the clinical picture of a pneumonia appears in many cases, it is often difficult to interpret the clinical signs when a pneumonia takes an atypical course, it being hard to differentiate between delayed resolution, carnification, abscess, gangrene, and tuberculosis. In the Charité in Berlin, de la Camp has been taking skiagraphs of the lungs of all pneumonia patients for the past few years, and has frequently found them of service in diagnosis, when the physical signs alone were of no value.

In the *Zeitschrift für klinische Medizin*, Vol. 63, 1907, Jürgens has published a series of *x*-ray findings, showing how, with their aid, a differential diagnosis can often be made between the above-mentioned conditions. During the stage of hepatization the affected area of the lung shows a uniform shadow in the *x*-ray picture, which gradually but steadily becomes lighter as resolution sets in, disappearing entirely in two or three weeks after the crisis. In cases in which dullness persists over the lung it is often difficult to distinguish between delayed resolution and the organization of an exudate. This difficulty lies in the fact that both conditions often exist together, and that the connective-tissue formation does not involve the whole pneumonic area, and may contract so quickly that physical examination cannot detect it. Thus, if a long-continued dullness finally disappears, we may be led to believe that the case was one of delayed resolution, while in reality the lung may contain an area of carnification too small to be detected by auscultation and percussion. If the case is one of delayed resolution the shadow will gradually but entirely disappear, even if it takes six to eight weeks. A shadow due to an area of carnification may get smaller, but will never become less intense; in fact, it may even become more intense. The persistence of the shadow does not necessarily mean carnification, as it may be due to other postpneumonic conditions, such as pleurisy with effusion and tuberculosis; here the clinical symptoms are of great aid, but the skiagraph is also useful. When, at the end of a pneumonia a tuberculous process develops, or a latent one becomes active, the physical signs may not be sufficient to differentiate it from delayed resolution or other complications. If they persist after the crisis in pneumonia of an upper lobe, and are due to delayed resolution, successive skiagraphs will show a gradual fading of the shadow, the latter finally disappearing entirely; if due to tuberculosis in the upper lobe the shadow may at first become lighter, but as the tuberculous process progresses it will again become more intense, never having disappeared entirely. Again, if the physical signs after a pneumonia of the base do not disappear after the crisis, and are due to delayed resolution, the shadow will finally disappear; if due to tuberculosis in another part of the lung new shadows will appear in these areas, while the shadow over the base will disappear entirely. When a tuberculosis begins so acutely that it clinically resembles a pneumonia, the *x*-ray picture is of little value at first, but when, instead of the shadow becoming uniformly lighter, light areas appear in spots, the picture is one of cheesy pneumonia.

With respect to such complications as abscess and gangrene, the clinical symptoms usually suffice to make a positive diagnosis, but the skiagraph verifies the diagnosis, and often shows us that the process is in a state of repair before there are any changes in the clinical symptoms. When gangrene complicates pneumonia the shadow of the stage of hepatization, instead of getting uniformly lighter, shows in one place an area which does not become less intense. If fluid is present in the cavity a dark line will represent its upper level in the *x*-ray picture, changing its direction with the change of position of the patient. In the case of gangrene, the clinical symptoms may persist for some time without much change, while the skiagraph will soon show an absence of fluid and that the gangrenous area is getting smaller.

Jürgens by no means claims that a diagnosis can always be made from the *x*-ray picture alone, and the clinical symptoms and history must ever be of considerable value. He emphasizes that the value of the *x*-ray does not lie in the taking of an occasional picture, but in taking successive ones of the same patient. Changes in the upper lobe are most easily interpreted in the picture, and it is this region which is most frequently the seat of delayed resolution and complications.

TREATMENT OF INFANTILE PARALYSIS.

NOTWITHSTANDING the substantial progress made in the science and art of orthopedic surgery during the past twenty years, the treatment of the paralyses following anterior poliomyelitis is still far from satisfactory. In most cases the paralysis diminishes for a time, sometimes for a long time, and, especially in the upper extremities, may entirely disappear; but this disappearance seems to be Nature's work in great measure, if not wholly, and how far it is aided by electricity, massage, and other therapeutic essays of the orthopedist is very uncertain. The effort is usually made to encourage the child to use the paralyzed limb as much as possible in the hope that through exercise the weakened muscles will be strengthened, the circulation in the limb will be maintained, and atrophy will be prevented.

An entirely different method is, however, urged in a recent article by A. B. Judson of this city, who counsels absolute rest so long as the paralysis continues to recede, even though this may take weeks or months. The argument by which he sustains his recommendation—the treatment has never been subjected to the test of actual trial—is as follows:

Disability from infantile paralysis, he says, is seen eight times as often in the lower as in the upper extremities, and yet in the early stage the paralysis is found in all parts of the motor nervous system. The muscles of the recumbent patient are in very moderate use and in a position entirely favorable to spontaneous recession of the paralysis. The arms and hands retain this advantage when the patient is erect, but the impaired muscles in the legs and feet give way at once when they meet the resistance of the weight of the body. They rapidly become elongated and attenuated, and could not well be placed in an attitude less favorable to restoration. When prescribed recumbency, however, Judson says, shall give to all parts the same environment, recession of paralysis will be equally encouraged in the lower and upper limbs, the disproportion of 8 to 1 will disappear, and the sum of deformity from this disease will be materially reduced. As soon as the disease is recognized, therefore, he would limit the patient to the recumbent position and keep him there so long as there was any possibility of further recession of the paralysis.

The objections to this mode of treatment, at least the difficulties of carrying it out, are evident, and are recognized by the author. During the months of treatment, while the paralysis is slowly diminishing, and until there is no hope of further improvement, he says, "the difficult task must be undertaken of keeping a child, well in every other way, off his feet at an age when he should be learning to walk. In some cases eighteen months should be occupied in this way. The common belief that such a patient requires exercise, especially of the affected limbs, will give rise to criticism and objections. A simple argument will not prevail in the family circle, and the physician's word will hardly prevent the little patient from having many a romp. And when the case ends there will be differences of opinion. If some lameness results, it may be said that the patient should have had more exercise, and if there is no disability at all, after the strict observance of recumbency, it may be said that there had been very little the matter with the child." We fear these difficulties will deter physicians from acting upon Dr. Judson's suggestion, and so putting his theories to the test of an actual trial.

THYMUS GLAND TREATMENT OF CANCER.

As a therapeutic agent the thymus gland has been but little used. It has been tried in the treatment of exophthalmic goiter, but probably possesses no specific action in this disease, as it has no distinct effect upon either the heart, the goiter, or the exophthalmos. Of late the gland has been tried on patients afflicted with cancer, and has produced, or at least been followed by, some remarkable results. In the July number of the *Annals of Surgery*, F. Gwyer reports its effect in a number of cases. He administered it only to patients considered beyond operation and beyond hope of cure, using the dried and powdered thymus of the calf in doses of one to four drams three or four times a day. The exact dosage is still experimental, the amount of action and reaction depending upon the amount of diseased tissue and its situation. If the growth be deeply situated and nonulcerating, all the elimination is through the excretory organs, and, disintegration once started, may, it is said, be so great that under treatment an autointoxication of such severity might ensue as to prove fatal. Patients with surface carcinoma, especially if the latter is ulcerating, seem to stand more medication with greater safety. During a course of treatment elimination should always be aided by keeping the bowels loose with salines, and the kidneys and skin active by giving plenty of fluids and frequent baths. In any case the amount of reaction, manifesting itself by weakness, loss of weight, etc., usually prevents the treatment from being carried out much longer than three weeks at a time. As Gwyer's work is but recent, most of his patients have had no more than one course of treatment, so that the full value of the thymus gland as a therapeutic agent in cancer is still unsettled. This much is certain, in the cases reported local improvement took place, the pain was diminished or abolished, and the cancer process was arrested or the size of the growth diminished; often, too, the general condition of the patient was improved.

Of course, Gwyer still advises operation in all operable cases of carcinoma, and does not claim that the thymus gland cures cancer; still the actual results obtained by him certainly warrant the trial of the gland in those patients with a tumor of moderate size, who absolutely refuse operation, and in those with cancers classed at present as inoperable and incurable, who have not been helped by other means.

THE MALARIAL PARASITES.

THE question of whether or not the three typical forms of malarial parasites, the tertian, quartian, and estivoautumnal, are really separate organisms, or whether they represent only variants of a single type, is one that has given rise to much discussion in the past, but concerning which comparatively few contributions have appeared of late. This is probably because most observers have come to the conclusion that it is safe to consider that the three forms above mentioned may be regarded as separate organisms, but there are still those, such as Celli and Plehn, who are loth to accept this view. The latter, for example, in a recent communication (*Deutsche medizinische Wochenschrift*, July 25, 1907), reiterates the opinion that the parasite of the tropics under other climatic conditions, assumes the forms we are accustomed to see in the temperate latitudes. In the course of his stay in Cameroon it was exceedingly rare for him to encounter parasites of types other than the pernicious form, and then only under circumstances, such as prolonged sojourn of the patient in the mountains, that made it seem possible that a metamorphosis of the original parasite had taken place. In support of this contention he cites a case recently observed in Berlin in which an official, just arrived from southwest Africa and suffering from black water fever, had in his blood great numbers of the tropical parasites. The condition proved somewhat refractory to treatment, and at the end of four weeks the clinical picture had changed to that of a tertian fever, and the parasites typical of this form had replaced the tropical organisms. Plehn thinks that it is out of the question that the patient acquired a second infection while under observation, and also considers that there is little foundation for the assertion sometimes made that in cases of this sort there is originally a double

infection, and that on removal to temperate latitudes the estivoautumnal parasites disappear, and the previously more or less latent tertian organisms dominate the picture.

Bacillus Anthracis on Horsehair.

While we can usually connect anthrax in man with some animal or animal product, reports on the direct bacteriological finding of the bacillus in the suspected material are rare. This is partly due to the fact that the infectious material is hard to trace. V. K. Russ reports in the *Wiener klinische Wochenschrift*, No. 22, 1907, a case of this disease in a man who worked with horsehair. At the autopsy the anthrax bacillus was found in the brain. At the place where the hair had been bought there was still some found in the bag from which the man had been supplied. On examining this, the *Bacillus anthracis* was found, grown on agar, and inoculated into animals with positive results. The methods employed in the search for the bacillus are based upon the facts that the spores are very resistant to heat, and are anaërobic. One of the best methods is that of Gruber, who inoculated sterile bouillon with wash water obtained by pouring sterile water over suspected material. The inoculated bouillon is kept anaërobically in Buchner tubes at a temperature of 37° C. for twenty-four hours, and then warmed in a water bath for an hour at a temperature of 60° C. Thus, all bacteria are killed; after the same procedure has been repeated on three successive days the bouillon tubes contain only dead bacteria and anthrax spores which are capable of germinating. Inoculation experiments with these spores after they have been plated on agar yield positive results. This method is far more satisfactory than when the wash water is heated only for an hour at 70° C. and then plated or injected into animals. In the latter case many other kinds of bacteria grow on the agar, and the animals usually die of some other infection than anthrax. The same is true if the wash water is sedimented after heating and the sediment then used for plating and inoculation.

The Function of the External Ear.

The most natural and the universally accepted view in regard to the function of the external ear is that it is intended to aid in the perception of auditory impressions by collecting sound waves and transmitting them through the external auditory meatus to the ear drum. The well-known observation that distant sounds are rendered more distinct if the hollowed hand is placed behind the ear in such a manner as to bend it forward, and that persons whose ears have been cut off suffer a considerable depreciation in the auditory function seems to confirm this assumption in regard to the part played by the external ear. Geigel (*Münchener medizinische Wochenschrift*, July 23, 1907), however, makes a somewhat different contention, and points out that in the experiment with the hand while the sound is considerably amplified if the hand is held close to, but not touching the ear, a quite noticeable increase in the strength of the auditory perception follows if it is brought into contact with the helix. This effect is also evident if the little finger is applied, instead of the thumb, although then the conditions are not very favorable for reflecting air waves into the meatus. Geigel therefore concludes that the function of the external ear is not to collect sound waves and direct them into the auditory canal, but that it transmits these waves direcly through its cartilages to the perceptive apparatus in the internal ear.

Sudden Death in Children During Infectious Diseases.

In many children suffering from infectious diseases the heart action is suddenly arrested and death ensues without any previous warning. Since this occurs, as well in diseases running a very mild course as in those running a severe one, it cannot be attributed to toxemia alone. Ad. Czerny (*Die Heilkunde*, No. 4, 1907) holds that this sudden death is due to anomalies of innervation of the vessels and heart, and to previous overfeeding of the child. He usually saw it in children of families of a nervous temperament or in children who, before they became ill, were considered nervous. A latent tetany can make itself manifest through some infection, and what holds good for this disease also holds good for other anomalies of the nervous system, especially those affecting the innervation of the circulatory apparatus. Czerny also noticed what seems to be of importance, that the children who died suddenly were usually fat. At autopsy they often showed nothing but a *status lymphaticus*, to which the sudden death is attributed by many observers. Czerny, however, holds that this view is wrong, as in his experience, based on the observations of many epidemics of various infectious diseases, these children were usually overfed, and it is the overfeeding which, according to him, causes the sudden death.

News of the Week.

Yellow Fever in Cuba.—New cases of the disease have appeared, both among troops and natives, in a number of places outside of Cienfuegos, the starting point of the present outbreak. The total number of patients so far reported exceeds twenty, and several deaths have occurred.

Plague in San Francisco.—Five cases of bubonic plague with four deaths have been reported to the San Francisco Department of Health during the past week. The patients, with one exception, were inhabitants of the poorer quarter of the city in the neighborhood of Chinatown. A steamer from which an infected sailor was taken is being kept in quarantine. Luckily, Schmitz, the mayor who tried to suppress the report of the former outbreak, is now in jail, so measures can be taken to prevent the spread of the disease. Plague has broken out in South Manchuria, and sixteen deaths have been reported.

Cholera in Russia.—An epidemic supposed to be of cholera has broken out in the Jewish quarter of Brest-Litovsk in Russian Poland. Forty cases and two deaths have been reported.

Investigating Dengue.—Passed Assistant Surgeons Joseph Goldberger and George McCoy, attached to the Hygienic Laboratory of the Public Health and Marine Hospital Service, were, upon the outbreak of dengue at Brownsville, Texas, detailed by the Surgeon-General to make a thorough investigation into the nature of this disease. They have established an efficient working laboratory and begun work, but just at present the investigation is temporarily interrupted, both officers having contracted the disease.

Anthrax in Orange County.—Several dairies in Orange County, N. Y., have recently lost cows through infection with anthrax, and the farmers are fearing a spread of the disease. The State Veterinarian has ordered the isolation of all exposed cattle, and great efforts are being made to prevent dissemination of the infection.

An Afflicted Town.—According to a despatch in the *New York Times* last week, an epidemic of what is thought may be cerebrospinal meningitis, though the symptoms are not typical of this disease, has had seventy-five victims between five and twelve years of age in Ridgway, Pa. There have also been over one hundred cases of typhoid fever in the town within the past two weeks.

Health Conditions in Manila.—According to the press despatches from Washington, the Manila Bureau of Health reports that during the month of June there were fewer deaths in the city than ever before since the American occupation began, and during the past six months there have been no epidemics of contagious disease.

Healthfulness of Sydney, N. S. W.—A despatch to *The Sun* from Sydney announces that the death rate of the city is the lowest of any other city in the world of the same size, being 10.62 per thousand. The population of Sydney at the last census was 524,100.

An Infallible Treatment for Typhoid.—The Mayor of Jersey City has been requested by one of the citizens of that city to make public a cure for typhoid fever that, like all domestic remedies, has never failed to cure in even the most desperate cases. The remedy consists of a tablespoonful of mixed tea, boiled in four cups of water, and taken cold without milk or sugar. The dose is a cupful a day and has both prophylactic and curative virtues.

Ice as a Medicine.—The Sunday regulations recently enacted in an Arkansas town, according to the interpretation insisted on by the Mayor, prohibit the sale of ice on that day, unless on the order of a physician, who is required to write a formal prescription for the commodity.

Cats to Exterminate Plague Rats.—The English Salvation Army is planning a campaign against plague in its colony at Muktipa, India, and as one measure has despatched from London twelve cats of good mousing proclivities in an effort to kill off the rats that are supposed to be the carriers of infection. It remains to be seen whether the Indian rat is not a match for the cat, and also whether the cats themselves, through their fleas, will not prove as great a source of danger as do the rats with their parasitic commensals.

Tests for Drunkenness.—The *London Globe* gives an account of how a licensed victualer of a small town, accused of being drunk on his own premises, produced medical testimony in his defence. The doctor said that immediately after the police visited the house defendant called at his surgery and asked to be tested for intoxication. In his presence the man walked perfectly along a straight line, stood upon one leg for three-quarters of a minute, repeated the word "hippopotamus" quickly and distinctly, and told the time by a watch to a quarter of a minute. The magistrates dismissed the case.

Reporting of Births in Illinois.—In a recent bulletin, the Illinois State Board of Health directs attention to the law, which provides a fine of not less than $1, nor more than $100 for failure to report births. The Secretary of the Board suggests that concerted action on the part of the State's attorneys whereby all violators of the law will be prosecuted, would render indifference to this particular law a very expensive matter to many physicians.

Attempted Evasion of the Illinois Medical Law.—A man was sentenced on August 9 to one year's imprisonment, the limit provided by the law, for misrepresentation regarding the examinations of the Illinois State Board of Health. He was also tried on the charge of practising medicine without a State license, was found guilty, and fined $100 and costs.

Gift to the Little Falls (N. Y.) Hospital.—By the will of Mrs. Nellie Bramer Smith, the Little Falls Hospital received a bequest of $8,000, to endow a bed in perpetuity in the female ward. Mrs. Smith was president of the hospital for several years.

The Sixth International Dermatological Congress will be held at the Academy of Medicine, New York, on September 9-14, 1907, under the presidency of Dr. James C. White of Boston. The treasurer of the Congress is Dr. George T. Jackson of New York, and the secretary-general, Dr. John A. Fordyce, 80 West Fortieth street, New York.

The Second International Congress of Physiotherapy will be held in Rome, October 13 to 16. The Italian Minister of Public Works has granted special traveling facilities to all members attending the Congress. The reduced fares apply to all lines, both on the mainland and on the islands. The Organizing Committee is authorized to issue to each member or associate, duly enrolled, a book of railway coupons. Each coupon entitles the holder to a ticket at from 40 per cent. to 60 per cent. reduction on the ordinary fare. As the book contains twenty tickets, available for any journey in any part of Italy, it enables members to make an extended tour in the country at greatly reduced cost. The coupons are valid for forty-five days—from October 1 to November 15, 1907. Ladies duly registered as associate members of the Congress and exhibitors may take advantage of the reduced fares. Applications for membership should be accompanied by the subscription of 20 francs for members, or 15 francs for associates, and should be sent to the general secretary, Professor Carlo Colombo, Via Plinio, Rome. The American secretary is Dr. Benham Snow of New York City. The president of the Congress is Dr. Guido Baccelli of Rome. The American president is Dr. Francis Bishop of Washington, and the treasurer of the American committee is Dr. Albert C. Geyser of New York.

British Columbia Medical Association.—At the eighth annual meeting of this organization held in Victoria on August 3, officers were elected as follows: *President*, Dr. J. M. Pearson of Vancouver; *Vice-President*, Dr. Corsan of Fernie; *Secretary*, Dr. R. Elden Walker of New Westminster; *Treasurer*, Dr. J. D. Helmcken of Victoria.

The Southern Medical Association.—The next meeting of this association will be held at Birmingham, Ala., September 24, 25, and 26, under the presidency of Dr. Henry Hagar Martin of Savannah, Ga. This Association is the Southern and Gulf Branch of the American Medical Association, comprising the States of Alabama, Georgia, Tennessee, Mississippi, Louisiana, Florida, and Kentucky. The secretary of the Association is Dr. Raymond Wallace, Chattanooga, Tenn.

The Fifth Censorial District Medical Society, which includes the counties of Adams, Cumberland, Franklin, Fulton, and York, Pa., held its second annual meeting on August 13. The following officers were elected: *President*, Major James Evelyn Pilcher of Carlisle; *Vice-President*, Dr. Rea of York; *Secretary*, Dr. Coffman of Scotland.

The Wyoming State Medical Society will hold its annual meeting at Lander on September 3, under the presidency of Dr. A. C. Godfrey.

Texas Medical Board.—Governor Campbell of Texas has appointed the following members of the State Medical Board: Drs. James D. Osburn of

Cleburne, Ed. Becton of Greenville, W. B. Collins of Lovelady, G. B. Foscue of Waco, J. J. Dial of Sulphur Springs, J. D. Mitchell of Fort Worth, M. E. Daniels of Honey Grove, O. R. Bragwell of Mineral Wells, W. S. Collins of El Paso, J. C. Crow of Dallas, and J. P. Rice of Fredericksburg.

Dr. Melvin R. Burnham has resigned the superintendency of the State Hospital for Tuberculosis at Ray Brook, and will practise in New York City at 320 Central Park West.

Obituary Notes.—Dr. Miles H. Nash, formerly of this city, died in Ridgefield Park, N. J., on August 13, at the age of seventy-four years. He was born in Norfolk, Va., and after receiving his medical degree from Jefferson Medical College in 1855 began practice with his father in Tallahassee, Fla. He served through the Civil War as surgeon, and at the close of the war came to this city. For eight years he was assistant to Dr. J. Marion Syms, and for twenty-six years he was connected with the Demilt Dispensary. A few months ago failing health compelled his retirement from active work.

Dr. Calvin Hostetler of Marcus, Ia., died on August 4, at the age of thirty-nine years. He was born at Marshalltown, Ia., and was graduated from the Sioux City College of Medicine in 1898, since which time he had practised in Marcus.

Dr. Ezra W. Abbott of Contoocook, N. H., died on August 12, at the age of eighty-six years. He was born in Contoocook and was a veteran of the Civil War. He was the first physician to reach President Lincoln after his assassination, and was in attendance upon him for the first twenty-four hours. He practised in Concord for many years, retiring from active work a few years ago.

Dr. Alexander McLean of Salt Lake City died in Pueblo on August 3, at the age of fifty-two years. He was born in Belleville, Ont., and came of a distinguished Scotch family. He was graduated from the medical department of the University of Michigan in 1877, and, after practising for a time in Leadville, Col., he moved to Salt Lake in 1889. Owing to an injury to the spine he was obliged to withdraw from practice about three years ago.

Dr. Louis A. Harris of Newburgh, N. Y., died on August 17, at the age of forty-nine years. He was a native of Annandale, N. Y., and was graduated from St. Stephen's College and the Albany Medical College.

Dr. P. R. Prendergast of Brooklyn died on August 16 at Cork, Ireland, as the result of injuries received about two months ago by falling down the companion way of the steamer on which he was sailing for Europe. He was landed at Cork and placed in a hospital, where he remained until his death. He was born in Clonmel, Ireland, fifty-seven years ago, and came to this country in early life. He was graduated from Jefferson Medical College in 1873, and, after practising in Philadelphia for three years, settled in Brooklyn.

Dr. Sorden McClure died at Philadelphia on August 8, at the age of thirty years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1899. He was connected with the ophthalmological staffs of Wills Eye Hospital and the Presbyterian Hospital.

Dr. Charles Stewart Wurts of Philadelphia died at Media on August 14, at the age of seventy-eight years. He was graduated from Jefferson Medical College in the class of 1854.

Dr. Samuel Beyea of New Rochelle died on August 18 at Roosevelt Hospital in this city, after an operation for gallstones. He was born in Westchester county forty-five years ago, was graduated from the College of Physicians and Surgeons, New York, in 1892, and served as interne in St. Luke's and the Sloane Maternity Hospitals.

PRIMARY TYPHILITIS WITHOUT APPENDICITIS.

To the Editor of the Medical Record:

Sir:—Referring to Dr. Byron Robinson's letter in the issue of the Medical Record of August 17, I regret that anyone should think for a moment that I claim any priority of belief that primary typhilitis may exist without appendicitis. Despite Dr. Byron Robinson's very instructive letter as to what he has observed and written, I believe that he and I are only reaffirming old truths which are forgotten, or ignored, by very many practitioners, alas, to-day, and especially by our surgical colleagues. But light is returning, let us hope and believe, and with it will also come the day when, as I think, operations will rarely be performed except for cases of perforation or localized abscess. Those of us who are conservative in this matter must bide our time and wait patiently until our misguided but beloved brethren come within our fold. When they do we shall pardon them for errors of *trop de zèle*.

Beverley Robinson, M.D.

Westport, N. Y.

OUR LONDON LETTER.

(From Our Special Correspondent.)

BRITISH ASSOCIATION—TUBERCULOSIS COMMISSION—SALE OF DISEASED FOOD—SCHOOL HYGIENE CONGRESS—HOSPITAL FUNDS, ETC.

London, August 2, 1907.

This is the week of the British Medical Association, which is holding its annual outing at Exeter, and has accepted an invitation to Sheffield for next year. As you have special reporters attending for you, I need not offer here any summary of its doings. This week also is the meeting of the Greater British Association for the Advancement of Science. This meeting is at Leicester, and the president is Sir David Gill, whose magnificent record as Astronomer Royal at the Cape is well known to all who are interested in that science. His address was equal to the occasion, contained an account of some of the minute measurements and calculations which are so important and to which he has given years of patient work. He said the stars were the crucibles of the Creator, and spoke of the discovery that a great part of space is occupied by two majestic streams of stars traveling in opposite directions and the amazing truth that the stars of both streams are alike in design, alike in chemical constitution, and alike in process of development. Then he pointed out that however vast these streams, comprising hundreds of millions of stars, the system to which they belong may be but one of millions more pervading the infinite, concluding with the old question: "Canst thou by searching find one God; canst thou find out the Almighty unto perfection?"

Lord Kelvin at once rose and moved a vote of thanks, and declared his intense delight at having been on a magic tour through the universe, personally conducted by the President, and carried, not on aeroplanes which would not fly, but on the strong, sure wings of the scientific imagination.

The second interim report of the Tuberculosis Commission, being part of the appendix to Vol. I, deals with the Pathogenic Effects of Bovine Viruses, and is written by Dr. A. Stanley Griffith. In the introduction he tells that inoculation experiments with bovine bacilli were made (a) to supply a basis of comparison with bacilli of human origin; (2) to determine the range of variation in virulence of different strains of bovine tubercle; (3) to test the susceptibility of various animals to bovine tubercle. Thirty different viruses of natural tuberculosis from the ox were employed. Fifteen different species of animals were experimented on. Clinical histories of many are reported illustrated by temperature charts. Post-mortem appearances are also recorded. The inoculation experiments with bovines show that milk can set up tuberculosis in guinea-pigs at the end of the first week and afterwards until the death of the cow. General tuberculosis in goats is set up by subcutaneous injections, and these animals seem from some experiments to be more susceptible to such injections than the calf. Other experiments show that the milk of a tuberculous cow may contain bacilli although the udder is not diseased, if the number inculating in the blood is large. The various species of

monkeys proved highly susceptible to the bovine bacillus. Feeding experiments were carried out on 318 animals of 15 distinct species. The most susceptible form a group including monkeys, rabbits, guinea-pigs, and some others. In these the infection is almost always fatal, the smallest dose setting up general progressive tuberculosis. In a second group the same result follows, but depends on the dose of the agent and the age of the animal; this group includes the pig, goat, calf, cat, and dog. These species show varying degrees of susceptibility, the young pig being most susceptible and the adult dog most resistant. The rat and the fowl appear to be insusceptible to tuberculosis by feeding. Comparing the effects of feeding by a single dose and by repeated doses Dr. Griffith seems to think that the single dose may set up the most extensive disease.

The results of this investigation are not calculated to allay the anxiety produced by the sale of diseased milk and meat. A "Medical Officer of Health" has communicated to the press during the last few months facts as to this sale which ought to be dealt with by sanitary authorities without delay. Of course some denials of his statements were forthcoming and even suggestions of exaggeration. But now the Medical Officer of Health has thrown off the veil of anonymity and repeats his charges. He is no other than Dr. A. Mearns Fraser, the distinguished Medical Officer of Health for Portsmouth, and in the August number of the *Nineteenth Century and After* he relates some of his experiences. By attending certain cattle markets between Portsmouth and London he obtained direct proof that milch cows in the last stage of tuberculosis were sold in open market, at nominal prices, for human consumption. His position enabled him to prevent the disposal of this meat in Portsmouth, but beyond the limits of that borough his authority did not extend, and there is no doubt it was sent to other populous places, including London. To put an end to this scandal it is necessary to force the central government to put pressure on the local authorities. The Board of Agriculture has considerable powers of dealing with cowsheds and milkshops; the supervision of meat and milk is vested in the Local Government Board. These two boards should work together. They have power to make notification of tuberculosis in animals compulsory, to require infected animals to be destroyed, and the cowsheds disinfected. This power has been exercised as to anthrax and other diseases, and Dr. Fraser has no doubt that if it had been extended to this case the trade in tuberculous meat and milk would not have attained its present scandalous proportions. Whether the legislature will put a stop to it depends on whether the public will insist that the remedy shall be provided without delay.

While partisan politicians are engaging in contradictions and recriminations the public weal is endangered. The public must therefore take a hand and force them to deal with this abominable scandal.

The International Congress on School Hygiene is after all to receive official recognition. I wrote you word a fortnight ago how the Board of Education had until then ignored it. It is now announced that the Lord President of the Council will, at the request of the King, open the Congress on Monday next. So the Board "saves its face." Although it "adheres to its decision not to issue official invitations to foreign governments it has arranged with the Foreign Office to take such steps as are likely to remove any misunderstanding," etc., etc.

The will of Sir Wm. Broadbent has been proved, the value of his estate being declared as £81,315 net. The will of Dr. Julius Dreschfeld was proved for £68,014 net.

The King Edward Hospital Fund has received a second payment of £10,000 on account of the residuary estate bequeathed by Lieutenant-General G. A. Baynes to the fund.

The Sunday Fund had a meeting yesterday. The committee recommended the distribution of £68,134 to the institutions benefiting. The executors of the late Mr. George Herring are ready to pay over £30 on account of his legacy. A second payment of £3,000 on account of the legacy of Mr. H. Lloyd was reported. Something like a warning to hospitals was decided on. It was proposed that any institution receiving a grant should obtain the approval of the council before entering into a contract which would increase the cost of maintenance. This was opposed by Mr. Sydney Holland as contrary to the policy of not interfering with the internal management of hospitals. Eventually it was resolved that hospitals benefiting should be invited to consult the council before increasing the cost.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

ANOMALY OF THE AORTA—PERFORATION OF THE SIGMOID—A SERUM REACTION IN NEPHRITIS—GELATIN IN CARCINOMA—OZONE IN WOUND TREATMENT—A FUNCTION OF THE PANCREAS.

VIENNA, June 28, 1907.

ANDREAS MAKAI has reported two cases of the formation of cord-like structures in the ascending aorta. One instance of this interesting abnormality was discovered at the autopsy on a man of sixty years dying of ulcerative endocarditis and secondary pyemia. The inflammatory process involved principally the aortic semilunar valves, and just above their insertion the vessel was bridged by a flat band 33 mm. in length, 4-6 mm. wide, and .5-1 mm. thick. The upper border of this band was rounded, but its lower portion was eroded through the extension of the ulcerative process. A similar case was observed at the autopsy on a man of sixty-five years, dying of apoplexy. Although there was only a moderate degree of arteriosclerosis, the left ventricle was much hypertrophied. The endocardium and valves were entirely normal; the cord, which resembled the one just described in situation and course, was 27 mm. in length, and 3-4 mm. in width. Its lower border was fused on both sides with the upper edge of the anterior semilunar valve. The relation between the cord and the valve was such that it appeared very unlikely that it could have been formed as the result of an embryonal or postembryonal pathological process. The pronounced hypertrophy of the left heart, which could have resulted only from the cord formation, was an interesting concomitant in the second case. The advanced age of both patients is also noteworthy, since this is not often observed in connection with congenital heart lesions.

Professor Schnitzler has successfully operated on a perforation of the sigmoid flexure, produced by a bougie introduced in order to relieve chronic constipation. The patient was in the habit of inserting a thick, hard-rubber bougie into his rectum several times a week. One day, as he was carrying out this procedure as usual, in the erect posture, he experienced a sudden pain in the lower part of the abdomen. No hemorrhage followed the withdrawal of the instrument. When Schnitzler saw the patient, about four and a half hours later, there was no pain nor vomiting, but slight rigidity was present on the left side. Rectal examination did not reveal any palpable injury, and was not followed by hemorrhage. The pulse was 80 and the temperature 38.1°. The elevation of the temperature and slight rigidity caused Schnitzler to suspect a perforation of the lower part of the sigmoid flexure, in spite of the absence of other symptoms, and he accordingly performed a laparotomy. On opening the abdomen a suppurative peritonitis of the lower portion of the abdomen was revealed and a perforation 3 cm. in length was found on the anterior wall of the sigmoid flexure, a palm's breadth above the peritoneal reflexion. Recovery was uncomplicated. While such injuries are not infrequent in the course of the treatment of rectal strictures, the present instance, occurring in a healthy intestine and without the exercise of much force, is interesting. The most important feature in such cases is the prompt resort to laparotomy, even in the presence of very slight symptoms.

Heinrich Schur and Josef Wiesel have studied a reaction in the blood serum of nephritics. Wiesel has shown that in pronounced nephritis, accompanied by hypertrophy of the left ventricle and elevated blood pressure, marked hypertrophy of the chromaffine system is regularly observed. This suggested that the high blood pressure might be associated with this hypertrophy of the chromaffine system. If this assumption were well founded, the secretion of the chromaffine cells—that is, the tension-producing substance—should be demonstrable in the serum of nephritics. Schur and Wiesel were able to prove this by means of the extremely sensitive test devised by Ehrmann. The method is very simple. The enucleated eye of a frog is immersed in the serum under examination, and the condition of the pupil is observed during several hours. While the serum of healthy persons and of those suffering from other diseases was without effect on the iris, all of the specimens obtained from patients with chronic nephritis caused pronounced, and often extreme, dilatation of the pupil, even when diluted twenty times.

Franz Hauer of Buda Pest has succeeded in causing marked improvement in cases of cancer by means of a new form of treatment, and in some instances, in which there could be no doubt as to the diagnosis, has even brought about a cure. Most of the cases were observed in hospitals and clinics in Buda Pest. The treatment consisted in injections of gelatin. These usually caused elevations of temperature at first, but this soon disappeared and general im-

provement followed. The ulcerated areas became clean, the pain grew less or disappeared, and the body weight increased. In one case the new growth disappeared completely, and in seven others almost complete disappearance was obtained, only a small mass persisting. In five of the forty cases treated no improvement was noted.

Alois von Gleich has tried a new method of wound treatment with ozone. Starting with the idea of using the active principle of peroxide of hydrogen, he was led to try the effect of liberating nascent ozone in the immediate neighborhood of the wound. This he did by treating commercial oxygen with the induction current and allowing the resulting gas to escape over the wound. Such a method is now easy to carry out, thanks to the perfection of modern electrical apparatus, and Gleich hopes in this way to extend the usefulness of a well-known and powerful antiseptic.

Loewi described before the Medical Association a new function of the pancreas and its relation to diabetes mellitus. In the normal eye the size of the pupil does not change when adrenalin is applied, but if the cervical ganglion has been removed twenty-four hours previously mydriasis results. Ten out of eighteen diabetics exhibited marked mydriasis, while of twenty-eight patients suffering from various other affections only two responded in this way. One was a case of occlusion of the pancreatic duct, and the other one of exophthalmic goiter.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 8, 1907.

Glottic Spasm of Nasal Origin in Adults.—Frank A. Conlon gives a short résumé of sixteen cases of spasm of the glottis of nasal origin, including one of his own. This is a spasm affecting all the adductor muscles of the larynx except the arytenoideus. Of the cases collected 57 per cent. were females and 43 per cent. males. In males the average age was forty-three years, in females thirty-two years. In seven of these cases the attacks occurred only at night, and in two others occurred most frequently at night, but in the remaining seven cases the attacks came on at no special time. In six of the cases no direct connection could be found with the sexual life or apparatus; menopause, two; disease of the sexual organs, one; masturbation, one; occurring directly after marriage, two. The results obtained showed the cause of this reflex in eleven cases to be congested or hypertrophied turbinates, in two cases polypi, in two cases atrophic rhinitis, and in one case chronic nasal catarrh. He believes the impulse arises in the termination of the sensory nerve, from a congestion or irritation of the surrounding tissue.

New York Medical Journal, August 10, 1907.

Angioneurotic Edema—Starling Loving describes five cases of angioneurotic edema and in all, though the histories of the patients prior to the appearance of the eruption varied, the symptoms immediately preceding and attending the development were in one important particular practically the same; in each there was abdominal distress, with more or less distention, due in the first partly to serous effusion, but mainly, in that case and in all the others, to accumulation of gas, followed in a few hours by the eruption which, though it appeared in different parts, presented in each essentially the same features. None of the patients had suffered previously from a similar attack, no evidence of heredity could be traced in any, and so far none has had a return. The skin was but slightly reddened and there was but little itching.

Addison's Disease in Children, with the Report of a Case.—D. Felberbaum and E. A. Fruchthandler report such a case occurring in a child twelve years old. From the entire picture and termination the case was undoubtedly one of Addison's disease, complicated by vagabondism. There were unusual findings in the stools, each microscopical field showing a great number of oval egg-like bodies, measuring about four times the size of a red blood corpuscle. The cytoplasm appeared as a thin but distinct rim around a large oval nucleus, giving the impression of encysted protozoa. Various well-known pathologists examined and studied the feces, but were not able to determine the nature of these bodies. In the case reported there was also eosinophilia, and a termination by severe convulsions and coma lasting eight hours. In a survey of the literature they succeeded in collecting twenty-five cases, including their own, and in conclusion called attention to some of the more important facts which are characteristic of the disease, as follows: 1. Extreme rarity of the disease in children under thirteen years of age. 2. It is as frequent in boys as it is in girls. 3. Mildness of gastro-enteric symptoms. 4. Peculiar condition of the hair. 5. Death usually under convulsions.

Mercuric Values in the Treatment of Syphilis.—William F. Bernart records experiments he has made with eighty-four ulcerative cases, dividing them into four classes of twenty-one patients each; in these he makes estimates of the mercuric values of the various treatments. The intravenous method is taken as a standard. In the intramuscular class the ratio between the time and the amount of medicine used when compared with the intravenous class was about the same, the time having been less than one-third greater, while the amount of medicine used was a trifle over one-fourth greater. There remains the deduction that the intravenous method is one-third faster than the intramuscular and that it requires one-fourth less medicine. The inunctions were a trifle over twice as slow as the intravenous injections. Any calculation as to the relative amounts of mercury used in these two methods would be mere guess work. The method by mouth is over four times more slow than the intravenous medication. The statistics and deductions given are an early step towards the final ascertainment of an accurate knowledge of the amount of mercury required for the absolute cure of lues.

Journal of the American Medical Association, August 17, 1907.

The Relation of the Hospital to Medical Education and Research.—W. H. Welch remarks on the advances made in medical education in this country during the last two decades, and says that it is above all in the laboratory teaching that the most striking progress has been made. The instruction in medicine and surgery, while it also has advanced, has hardly kept pace, and the clinic lags behind the laboratory more than it should. He believes that it is the duty of our medical schools to furnish students with clinical teaching comparable to that given in the laboratory. The difficulties now come from the hospitals. There are few medical colleges that have their own hospitals, and the others must look to the outside public hospitals for aid. Welch shows how groundless are the objections made to the use of public hospitals for medical instruction, and how the plea for such utilization is in the interest of the public and the patient. The hospitals also, as he has pointed out elsewhere, should serve for the higher clinical training that is attained only after a still longer apprenticeship. In conclusion, he pleads also for the encouragement of research in our hospitals, but it is to the special clinical laboratories that we shall have to look for the more penetrating insight into the causes and nature of many diseases.

Phototherapy.—J. F. Schamberg gives an account of the present status of phototherapy, including the latest views and results of studies on the bactericidal action of light, its penetration, and the histological changes effected. While the rays toward the violet end of the spectrum possess the highest bactericidal efficiency, this is shared to some extent also by the more penetrating rays near the other end. The discovery made in 1900 that the lower forms of life can be rendered more sensitive to the action of light by the use of chemicals is mentioned as having influenced the more recent studies by directing observers to attempts to increase the chemical activity of the more penetrating rays. As regards histological changes, it is generally agreed that light causes marked dilatation of the superficial and deep cutaneous blood-vessels, with exudation of leucocytes, increase of connective tissue cells, and a swelling of the collagen. There is an epidermal hyperplasia and abnormal cornification. The treatment of lupus vulgaris is the present dominant field of phototherapy, but it has its true value also in other conditions—lupus erythematosus, acne, alopecia areata, flat vascular nevi, certain forms of eczema, leg ulcers, etc. In lupus erythematosus and alopecia areata it has been of special service. The different forms of lamps are noticed, especially the mercury vapor lamp, with the use of which Schamberg gives his own experience. He thinks it is most effective in alopecia areata, leg ulcers, and certain forms of eczema. The light is rich in chemical rays, but lacks deep penetration. It gives a broad volume of light, applicable over large areas, and the grade of light erythema desired can be produced and even predetermined by the distance and duration of the exposure. He concludes that such phototherapeutic measures are not to be regarded as panaceas, but as aids to other approved agents in the treatment of certain cutaneous diseases.

Bier's Treatment.—Willy Meyer eulogizes Bier's method of stasis hyperemia in the treatment of infectious surgical disorders, referring to Bier's work and also giving the results of his own experience. He has found the method of the greatest value in the treatment of tuberculous joint affections, especially in the early stages, and in the lower joints of the extremities. While it is possible to apply the method to the shoulder by means of special apparatus devised by Bier, it is unfortunate that no one has

yet succeeded in producing venous stasis of the hip. The method unquestionably requires much study and experience to adapt it to the needs of individual cases, and this is even more true in the management of acute surgical infections other than tuberculosis. He gives a long list of such conditions in which he has used this method successfully, including its application as a prophylactic measure against threatening meningitis. He says that its prophylactic use deserves to be especially emphasized. The hyperemic treatment of incipient pulmonary tuberculosis is also mentioned as of importance. Bier's method is a new and most powerful weapon against disease, enabling us to treat many chronic and acute surgical affections more conservatively and with less discomfort to the patient, and with far better functional results than are obtained by any other method thus far discovered in medical and surgical therapeutics.

Medical Education in the Army.—Colonel P. F. Harvey remarks that the impression still largely exists, even among well-educated people, that in case of war there would be an ample supply of skilled physicians and surgeons at once available for service. Those holding this opinion are unaware of the essential requirements of the military surgeon, who, in addition to his purely professional duties, must be acquainted with the complex subjects of military medical administration, including the customs of the service, the hygiene of posts and camps; the service of the front and rear during and after a battle; the establishment of field hospitals and dressing and ambulance stations; the school of the soldier; the hospital corps drill; methods of removing wounded; inspection and muster; and the preparation of the multiple reports, requisitions, etc. The all-around, competent medical officer has to have special training and is not at once improvised from the recent graduate or even from the experienced civil practitioner. Like most other governments, the United States has an Army Medical School, located in Washington, in which those entering the medical corps of the army receive their special instruction, being taken first as contract surgeons, and after graduation filling existing vacancies in the medical department. Medical officers of the militia are also eligible for admission and Harvey thinks that their attendance should be encouraged. The instruction covers all subjects that the medical officer is required to know in the ordinary course of his duties, and its practical outcome has been to increase greatly the efficiency of the medical corps. He also gives a brief résumé of the general educational system adopted in the United States Army, which may, in time of peace, be regarded as a vast educational institution. Military hygiene is one of the subjects studied at West Point in the infantry and cavalry schools, and in the garrison schools, and the promotional examinations of officers up to captain in the infantry and cavalry and of lieutenant in the artillery include this subject.

The Lancet, August 3, 1907.

Mobile Kidney, with a Description of an Operation for Anterior Nephropexy.—E. Stanmore Bishop says that the cases in which practical men are interested fall into the category of "mobile" or "wandering" kidney, are not surrounded by peritoneum, and their excursions take place entirely behind the paricta peritoneum in the loosened subperitoneal connective tissue. Regarding this variety there are only four points on which writers appear to be agreed, viz., that such a condition actually exists, that it is most frequent in women, that it is most frequently seen on the right side, and that it is very frequently associated with neurasthenia. After quite an exhaustive review of the literature, he describes his operation as follows: An obliquely transverse incision is made through the muscles of the abdominal wall outside the rectus muscle. This gives free access to the renal fossa on the right side. The liver being lifted, the stomach drawn inwards, and the hepatic flexure of the colon depressed by broad retractors or large flat sponges, the parietal peritoneum is divided transversely over the lower fourth of the kidney. The two peritoneal edges being held apart, a curved incision, concave upwards and outwards, is made in the proper capsule, and the lower segment of this loosened from the anterior renal surface down to its inner and lower extremity. This capsule remains attached to the posterior surface of the organ. Its flap is turned downwards and inwards, leaving the raw surface of the kidney exposed for a corresponding distance. Two or three sutures attach this loosened edge of the capsule to the fascia beneath. The peritoneum is sewn up by catgut. The anterior surface of the lower leaflet of the true capsule is now in contact with the posterior abdominal wall, and the posterior surface of the peritoneum is lying upon it and upon the bared lower anterior renal tissue. A long straight needle, armed with iodized or chromicized catgut, No. 3, is pushed directly backwards immediately below the ureteral insertion until its point emerges behind; another needle carries the opposite end of the same thread, and is pushed through one centimeter below the first. When both needles are drawn through the thread is tied over the muscular layer behind the peritoneum, capsule, and posterior tissues are united on the inner side of the lower pole of the kidney. Another pair of needles is placed in a similar manner so as to carry a loop of catgut below the inner lower angle. Two or three more carry loops below the kidney. All these pass through peritoneum, capsule, subperitoneal connective tissue and muscles. When drawn tight and tied the kidney will be supported by a row of sutures which do not penetrate its substance, but which effectually fix it. The closure of the abdominal wall in tier fashion completes the operation.

Iodine as an Antidote in Carbolic Acid Poisoning.—John Maberly reports three cases. The first two recorded demonstrate the value of iodine for the ill effects of carbolic acid on the mouth and throat, when administered soon after the poison has been swallowed and before any symptoms which can be distinctly traced to its effects on the stomach and intestines have had time to develop. The third case had all the toxic effects of the poison fully developed, as well as distinct signs, in the tympanitic abdomen and the dark and slimy stools, of the poison having reached the stomach and intestines and set up changes there. The administration of iodine can be safely credited with the happy result obtained.

Notes of a Case of Addison's Disease in a Negress.—R. Scheult records such a case because of its rarity in the dark-skinned races.

The British Medical Journal, August 3, 1907.

Acute Enteric Intussusception with Apparent Reduction by Irrigation: Abdominal Section and Fatal Result.—This interesting case is reported by William Templeton. A boy three years old had an acute enteric intussusception. There was slight general swelling of the abdomen and tympanites, with a quite definite elongated swelling, not at all sausage-shaped, about two inches long and one inch broad, lying obliquely downward and inward in the left iliac region, dull on percussion. Rectal examination showed nothing abnormal. A pint of warm water was gradually injected into the bowel, which was followed by a disappearance of the tumor. On the day following the abdomen was found to be again distended and tympanitic, and the tumor was again present as before; it was hard and dull on percussion, but not tender. A large enema of warm water was injected and the tumor again disappeared completely. Three hours later it reappeared. While the child was being prepared for abdominal section, and while he was under chloroform, an enema was again injected, with a complete disappearance of the tumor. In a few moments it reappeared. At operation an invagination of the bowel was found, about two inches or so in length. This was easily reduced. The child recovered well from the operation, and passed a large, distinctly fecal motion; but thirty-six hours after the operation he became collapsed and died. This case is interesting in relation to the question whether cases of acute intussusception should be operated upon as soon as a definite diagnosis is established, or whether irrigation or inflation of the bowel should first be tried. In the enteric variety, which forms about 30 per cent. of all cases, irrigation cannot possibly be of any use, and may, as in this case, cause delay in resorting to abdominal section.

Iodine and Typhoid Fever.—David Walsh states that he gives iodine and carbolic acid in all cases of typhoid fever that come under his care, with uniformly good results, a rapid general improvement, and with an absence of complications. His directions are to put one minim of pure carbolic acid and two minims of tincture of iodine into a tumbler of water, and let the patient drink as much of this both day and night as he wishes. It would be interesting to have the efficacy of this treatment investigated in a prolonged series of cases at some large metropolitan hospital or by a collective committee.

Berliner klinische Wochenschrift, July 29, 1907.

Concentration of the Immune Bodies in Diphtheria Antitoxin.—Brieger and Krause describe the following method, by means of which they were able to concentrate diphtheria antitoxin to a very great degree: The serum was diluted with an equal bulk of distilled water and precipitated with neutral ammonium sulphate. The precipitate was dissolved in 10 per cent. watery glycerin solution and again precipitated with an excess of sodium chloride. This precipitate was separated and tested for protective power. It was found to contain

no antibodies, whereas the solution still possessed its original strength. Carbon dioxide was passed through the fluid and the resulting precipitate was filtered off and tested again with a negative result. The filtrate was found to be of great potency, and on determining its nitrogen is was discovered that through the several precipitations 75 per cent. of the total nitrogen had been removed, without any impairment of the immune bodies. By the addition of diluted formic acid a further precipitate could be obtained which did not appear to be directly related to the immune bodies. Attempts at concentration by dialysis were not altogether successful.

Gangrene of the Scrotum.—Kettner, in discussing this condition, describes the case of a man of thirty-five years who acquired an erysipelatous infection of the scrotum as the result of abrasions produced by the friction of a new pair of trousers. In consequence of this three-quarters of the skin of the scrotum and some of that covering the penis became necrotic and sloughed away. The tissues cast off included, in addition to the skin, the dartos, most of the septum, and the loose connective tissue lying between the dartos and the testicle. In the treatment of such defects it is necessary to provide the denuded organs with a more substantial covering than that afforded by spontaneous epidermisation, and for this purpose pedicled flaps taken from the thighs or inguinal regions are the most suitable. Unless provision is made in this way for a thick covering, the patients suffer from hyperesthesia of the organs to a degree that may be altogether incapacitating.

Münchener medizinische Wochenschrift, July 23, 1907.

The Operative Treatment of Carcinoma of the Rectum.—Berndt, in discussing this subject, says that the two chief dangers of the extirpation of the rectum are intestinal gangrene and infection of the abdominal cavity and the wound. Better results than those obtained at present are to be expected only if these two dangers are avoided with certainty. Even the most accurate anatomical knowledge of the normal blood supply of the rectum does not insure against gangrene, for it is impossible in the living patient to ascertain the individual peculiarities of vascular distribution, etc., with sufficient accuracy to guard against serious impairment of the blood supply. It is, therefore, better to operate in two stages and to choose as high a portion of the gut as possible for implantation into the anus. Infection of the abdominal cavity and wound can be avoided with absolute certainty only if the intestine is not severed or opened within either of these. The plan of operation he proposes is as follows: The anus is completely closed by suture and then the rectum is exposed through an incision along the left border of the coccyx and sacrum; the wound is packed with gauze, and the intestine, with its lymphatic glands, is exposed and loosened from its attachments through a laparotomy incision. The portion to be resected is pushed out through the sacral wound and the peritoneum is sutured carefully about the portion drawn down. This terminates the first act of the operation, and the second is performed as soon as intestinal gangrene has begun. It consists in removing the growth, together with the gangrenous portion of the intestine, by means of the cautery. The upper stump is drawn down and is sutured to the anus. If the accumulation of gas or feces renders it necessary to open the intestine before it is time for completing the operation, this may be done without risk of infecting the wound, as the portion of gut to be removed can be drawn out for some distance and its contents be received in a suitable receptacle without soiling of the wound area.

Removing the Appendix in Gynecological Operations.—Pankow is of the opinion that at all laparotomies for gynecological purposes the appendix should be removed. As a result of careful study of 147 appendices that were removed at pelvic operations for a great variety of conditions, distinct evidence of appendicitis was discovered in eighty-two cases. The author estimates that appendicitis is much more frequent in women than has been generally accepted, and that about 60 per cent. of all women are affected during the period of sexual activity. Lesions of the appendix also furnish a potent source of inflammatory conditions of the pelvic organs, and are not rarely the cause of sterility induced through stenosis of the tube. A very large proportion of the pains in the right lower abdominal quadrant, formerly ascribed to ovarian conditions, is the result of a previous acute appendicitis.

Deutsche medizinische Wochenschrift, July 25, 1907.

Automobile Injuries.—Kettner says that coincidently with the development of methods of transportation of increased rapidity a corresponding augmentation of traumatic injuries has taken place. A considerable variety of lesions is already ascribable to the use of the automobile, and presumably the number of casualties of this nature will undergo a steady increase. A characteristic form of injury is the fracture of the forearm, which is not infrequently caused as the result of back-firing in cranking the motor, and this will be caused to disappear only when methods for starting the motor automatically have been evolved. A very unusual injury resulting from the introduction of the automobile omnibus is reported by the author. The patient was a boy of thirteen years, who, in stepping from a street car, was run down by a rapidly advancing motor omnibus. The front wheel of the vehicle, in passing over his left leg, completely stripped from it all of the skin and subcutaneous tissues from the ileum in front and gluteal region behind to the first and second toes, so that the muscles and tendons were all exposed, as in an anatomical dissection. The patient's condition was fairly good, so that the attempt at conservative treatment was deemed justifiable. The skin flap was cleansed and wrapped around the limb again, but on the fifth day it was seen that the huge flap was becoming gangrenous and it had to be removed. During the next eight weeks the patient made satisfactory progress, and some form of skin-flap transplantation was being considered, but a change for the worse occurred and, on account of the boy's general condition, amputation at the hip was performed. A month later he died of bronchopneumonia.

Experimental Syphilis in Rabbits.—Mühlens says that numerous observers have now succeeded in inducing in rabbits parenchymatous keratitis by inoculation with syphilitic material. He himself was able to demonstrate spirochetes in great numbers in the eyes of two animals inoculated six weeks previously with juice from a gland containing the organisms. A monkey (macac) inoculated with scrapings from the rabbit lesion fourteen days later exhibited a typical primary lesion of the eyebrow, and scrapings from this chancre gave rise to a typical keratitis about two months after having been inoculated into a rabbit. Preparations from this lesion again exhibited the spirochetes. This is the first instance, according to the author, in which the chain of transmission of the organism from man to rabbit, to monkey, and again to rabbit has been carried out. Mühlens has also been successful in inoculating the rabbit's cornea with material from the lungs and adrenals of a child dying of congenital syphilis.

French and Italian Journals.

Tuberculous Testicles in Children.—G. Poissonnier says that tuberculosis of the testicle in children may occur at any age, even in the fetus, or the child of a few days old. It is more frequent under two years, and becomes less so up to the time of puberty. It is generally primary in the testicle, secondary in the epididymis, which is the opposite of the localization in the adult. It is usually single. Traumatism and masturbation may be factors in its etiology, but the principal one is heredity. It may be propagated to distant parts of the body, as the lungs, or may occur with intestinal tuberculosis. The symptoms are the same as those of orchitis in the male, the process being acute or chronic. The testicle is swollen, tender, and painful. At one portion the testicle becomes adherent to the skin, an abscess forms and a fistula results. If more chronic the abscess may be walled off by fibrous tissue, and may never open externally. The only complications to be expected are generalization by means of the circulation or the lymphatics. The inguinal, iliac, and lumbar glands are generally involved. The prognosis is good, since cicatrization occurs and a certain amount of testicular tissue is usually left. For this reason treatment should be conservative, castration not being advisable. General hygienic measures such as are applicable to other forms of tuberculosis are important. Puncture of the abscess, with injection of iodine or iodoform, curettage, and drainage are the best surgical measures.—*Gazette des Hôpitaux*, March 16, 1907.

Diagnosis of Lingual Tuberculosis.—Riccardo Dalla Vedova says that the localization of tuberculosis in the tongue is quite rare. He gives the histories and microscopical examination of portions of the growths in two cases, and deduces from these the opinion that the only important diagnostic point is obtained by the examination of a portion of the growth removed from the base of the ulcer. If a portion be removed from the side, we may find epithelial developments that will be quite suggestive of epithelioma. The three conditions that are to be differentiated from tuberculosis are syphilis, epithelioma, and

actinomycosis. When the ulcer is single, and there is no other focus of tuberculosis in other organs the appearances and symptoms may be the same for the three forms of ulcers. The author believes that there are authentic cases observed in which the ulcer of the tongue was primitive, and not a secondary complication of pulmonary, or gastrointestinal tuberculosis, because we have records of complete cure by removal of the growth in the tongue. The ulcer may be located in the mucosa or the parenchyma of the tongue. The tuberculous ulcer is generally placed at the margin or tip of the tongue, resulting in the appearance of a little nodule of a white or yellow color, which becomes caseous, and ulcerates, leaving an oval or round ulcer, with a grayish-yellow base that is not very firm, irregular borders, and slight infiltration of the edges. There is swelling of the neighboring lymphatic glands. The ulcer may be deep, infiltrated, and give considerable neuralgic pain, while it hinders the movements of the tongue in mastication and speech, and the general health is affected. The syphilitic and epitheliomatous ulcers are very similar, and there is no one symptom that may not be the same in different cases of the three forms. A bacteriological examination of the mouth secretions will not be reliable, so that the only diagnostic point of value is the microscopic examination of removed tissue.—*Il Policlinico*, March, 1907.

The Phagocytic Power of the Blood in Infants.—Gaetano Finizio has modified the methods of Leishmann and Douglas for examination of the phagocytic power of the blood. He tested the blood in an infant attacked by purulent pleurisy originating from the staphylococcus aureus, and that of a baby suffering from slight dyspepsia. Pus from another source was also used for purposes of comparison. He found that in both babies the index of phagocytosis was higher to the pus from the pleura than to the compared pus. That of the baby with empyema was always higher than that of the other baby. In both babies the phagocytic index was within the limits given by Wright. The author concludes that the index is lower for a virulent staphylococcus than for a less virulent one. It has been observed that virulent staphylococci are slightly subject to the influence of phagocytosis. The phagocytic index is higher in healthy children than in those that are ill.—*La Pediatria*, March, 1907.

Leukemic Retinitis.—Rochon-Duvigeaud says that although retinal hemorrhages are frequent we are ignorant of their pathology, since we are only able to observe the microscopic changes on the post-mortem table. Ophthalmoscopic observations show only the gross changes and are at best unsatisfactory. The blood examination in such cases has not been carefully studied. Such hemorrhages are common in leukemic patients without giving marked symptoms, or loss of sight. In leukemia the blood is much altered in its cellular contents. There are present a large number of granular leucocytes in myeloid leukemia, a pure splenic form. There are also a large number of mononuclear leucocytes. Such lesions are easily cured by measures that succeed in curing the disease, and the retinal changes undergo retrogression. The cause of these lesions seems to be the obstruction of minute vessels by masses of leucocytes which pass very slowly through the vessels. This occurs especially in the capillaries and the beginnings of the veins where the blood current is slow.—*La Presse Médicale*, April 27, 1907.

Operative Treatment of Phlebitis.—Senechal advocates the operative treatment of phlebitis as the most rational one to be used. These inflammations of the veins are acknowledged to be infectious. Excision of the inflamed area will bring about a cure in from two to three weeks, where medical treatment would mean months of disability. At the same time recurrence, when operation is promptly done, will be prevented. Operation is followed by no accidents or bad results, and is not dangerous to the patient. The author has made many resections for phlebitis and has never had any bad results. The treatment varies with the size and severity of the inflammatory process and its location. The general technique consists in absolute asepsis; incision of the skin, linear if only one vein is affected, lenticular when many are involved, with the removal of the diseased skin; ligature of the efferent veins beyond the thrombosis, ligating in healthy tissue, not less than three centimeters from the clot. The vein is then removed between the ligature and a pair of compression forceps and followed by closure of the skin wound. The author describes minutely the technique to be used in various kinds and locations of thrombosis.—*Gazette des Hôpitaux*, May 10, 1907.

Responsibility of Hysterical Patients.—Crocq tells us that the responsibility of hysterics varies considerably with the especial case observed; in each case we must consider the acts and circumstances, and whether the patient acts in one of his attacks or in a lucid interval. Hysteria results from a condition of hyperimpressionability, with diminished cerebral control and hypersuggestibility. There is a distinct perturbation of the mental state. Hysterics differ in the gravity of the mental state, according to the type of mental trouble. When there is little brain trouble the patient may be regarded as responsible. If there is marked mental loss of equilibrium the patient becomes absolutely irresponsible. Acts committed in an attack are not responsible acts, while between the attacks the patient can comprehend and understand his acts. In some states there is an entire loss of consciousness, insensibility, and disorientation. Hence all such acts must be carefully studied, as there are very great difficulties in determining responsibility.—*La Revue Médico-Sociale*, May 10, 1907.

Ehrlich's Diazoreaction in Eruptive Fevers.—Collet says that the diazoreaction depends on the coloration obtained, a cherry red being the characteristic color in typhoid fever. Normal urine gives a yellow coloration. Certain medicaments, such as guaiacol, creosote, and benzonaphthol produce this reaction when eliminated by the urine. It is also obtained with many aromatic bodies. The presence in typhoid fever may be explained by intestinal resorption of putrid products. Yet it is lacking in gastric diseases, cirrhosis of the liver, hepatic insufficiency, lesions of the pancreas, etc. It is generally absent in nonfebrile diseases. It is present in the following febrile diseases: Tuberculosis, typhoid fever, eruptive fevers, infectious maladies, and acute respiratory difficulties. In measles it is generally positive, but there are cases in which it is lacking. In these cases the tint varies with the amount of fever. The diazoreaction has no relation to the intensity of the eruption, and is present for some days, growing less as the eruption fades. It appears before the rash. In scarlatina it is habitually negative. In diphtheria it is negative. It is absent in serum eruptions. Thus it is not a diagnostic sign alone, but may aid in diagnosis in certain diseases.—*Lyon Médical*, June 30, 1907.

Surgical Treatment of Radical Paralyses of the Brachial Plexus.—Codivilla considers it remarkable that the majority of paralyses of the brachial plexus are not cured, even when the causes are slight and easily relieved. In these cases he believes that the pressure of the transverse processes on the nerve roots is a factor in making the paralysis permanent. In such cases it is advisable to remove the transverse processes so as to throw the two contiguous foramina into one and to give more space to the nerve roots. He does not accept the theory that the effect of lesions of the roots of brachial plexus is greater on the anterior gray horns of the spinal cord than lesions of the trunks of the nerves or peripheral branches, or that the stretching of the roots makes its effects felt immediately on the gray horns of the cord.—*La Riforma Medica*, April 27, 1907.

Medical Treatment of Tuberculous Adenitis.—A. Robin advocates general, local, and hydromineral treatment. The general treatment consists of nourishing food, especially gelatinous compounds, arsenic, and codliver oil. The local treatment consists of friction with an ointment as a placebo to content the relatives, radiotherapeutics as the preferred remedy, and injections of arsenic when this cannot be given. The hydromineral treatment consists of a sojourn at a spring that contains sodium, magnesium, and calcium, with residence in the open air. This is followed by an arsenical cure at other springs, and a life at the seaside for the summer, with a warm climate for the winter. The x-rays cause an isolation of the glands, and a slow diminution in size. The integrity of the skin must never be compromised.—*Le Bulletin Médical*, June 29, 1907.

Neurasthenia and Autointoxication. — Archangele Memella believes that the name neurasthenia is inexact and insufficient to express the conception of this neurosis. By many it is not admitted that neurasthenia can ever be congenital, as has been claimed by some, although an intolerance for the organic poisons can be inherited. Neurasthenia is not a well-defined disease, nor a morbid entity, but a syndrome. In general there is a toxemia, resulting from altered metabolism in neurasthenic cases, and this toxemia is of gastrointestinal origin. Nervous dyspepsia and gastric neurasthenia are the same condition under different names. There is no reason for seeking for an especial pathology. Neurotic symptoms are generally of chemical origin. Some reflex nervous symptoms result from the ingestion of certain food substances. The same may be said of cephalalgia. The neuroses and many psychoses are of autotoxic origin, and especially of gastrointestinal origin.—*Giornale Medico del Regio Esercito*, June, 1907.

Book Reviews.

THE EFFICIENT LIFE. By LUTHER H. GULICK, M.D., Director of Physical Training in the New York City Schools. New York: Doubleday, Page & Co., 1907.

IN this book, which is rather a series of sensible talks on how to make the best of hygienic conditions as we find them than a serious treatise on the care of the health, the author shows how each one can work, with the means at his command and against the odds that confront him, so as to get all out of life that there is to get in the way of physical fitness and thus to accomplish in the best possible way what there is to be done. Dr. Gulick is an apostle of cheerfulness and recognizes the power there is in a happy and contented mind to keep the body well. He is not content merely with a "don't worry" admonition, but shows how the mind can in turn be influenced by the body and how the man with the blues can, if he will but put on the physical mask of cheerfulness, force his mind into correspondence with the joyous acts of the body. There is a great deal more than this in the book and it is all good. The advice given is practical and sensible, and it is given in the form of suggestion, not preachment, therefore will more probably be followed by the reader.

HISTOLOGICAL OBSERVATIONS ON SLEEPING SICKNESS AND OTHER TRYPANOSOME INFECTIONS. By F. W. MOTT, M.D., F.R.S. (From the Pathological Laboratory of the London County Asylums). New York: William Wood & Co., 1907.

THIS volume of forty-five pages and eleven plates contains Dr. Mott's contribution to the Reports of the Sleeping Sickness Commission. There is no doubt that the *Trypanosoma gambiense* is the cause of the disease in question and that the usual mode of infection is a biting fly, the *Glossina palpalis*. The chief changes produced by the *Trypanosoma* are in the central nervous system, and they are so characteristic that they may almost be called specific. These changes are here described; but how they are produced is not yet known.

RACE CULTURE; OR, RACE SUICIDE? A Plea for the Unborn. By ROBERT REID RENTOUL, Doctor of Medicine; Member of the Royal College of Surgeons (Eng.), etc. London: The Walter Scott Publishing Company, Ltd., 1906.

THE present work is an enlarged edition of "Proposed Sterilization of Certain Mental and Physical Degenerates," published about four years ago. In it the author calls attention to the large and steadily increasing number of degenerates of all kinds—alcoholic, suicidal, homicidal, lying, kleptomaniac, sexual, and neurotic—at the same time he proposes certain measures to check the increase in the number of these degenerates, and simultaneously to prevent innocent children from being cursed by some parental blemish. The book is powerfully written by a man capable of thinking for himself and who is not afraid of his own conclusions. That the views expressed in this volume will meet with intense disapproval in some quarters is more than likely; particularly will this be the case among those who are unaccustomed to think, or who blindly believe that "whatever is, is right." The causes of national degeneracy as depicted by the author are true for any country; and the remedial measures which are here advocated for the same will also apply to most countries. The book is instructive and stimulating; it is written in a style both vigorous and lucid, and it deserves the attention of all who are interested in the human race.

CLINICAL PSYCHIATRY. A Textbook for Students and Physicians. Abstracted and Adapted from the Seventh German Edition of Kraepelin's "Lehrbuch der Psychiatrie." By A. ROSS DIEFENDORF, M.D., Lecturer in Psychiatry in Yale University, Member of the American Neurological Association, of the New York Neurological Association, of the New York Psychiatrical Society, and of the American Medico-Psychological Association, etc. New Edition, Revised and Augmented. New York: The Macmillan Company; London: Macmillan & Co., Ltd., 1907.

THE first edition of Dr. Diefendorf's convenient book appeared in 1902, and was reprinted in 1904. It was based on the sixth edition of Kraepelin's "Lehrbuch der Psychiatrie." The present edition is a thorough revision and an amplification by a hundred and forty-two pages. It is based on the seventh edition of the Lehrbuch, and comprises, as before, Professor Kraepelin's classification, phraseology, and terminology, and a translation of some of the context. The author has given much more space than previously to the psychopathic states, and more elaborate treatment of such important subjects as the mental states in hysteria, epilepsy, neurasthenia, and the traumatic neuroses. He has also introduced many important changes in his symptomatology. The chapter on Methods of Examination, as rewritten, merits a word of special praise and will be found of practical clinical value. The experimental methods of the psychiatric laboratory, however, are not described: these may be found in Kraepelin's original works. A chapter on Psychopathic Personalities, comprising born criminals, the unstable, the morbid liar, and swindler, etc., has been added. The treatment of the various psychoses is fairly discussed. Those who have followed the work of Freud, Jung, Bleuler, and others would doubtless have been glad if some reference had been made to it to bring the book quite completely up to date, even if such work is not strictly Kraepelinian. For the benefit of psychiaters of the old *régime*, and for the general practitioner, a glossary of many of the terms and phrases employed would have been of service. The book, however, is, on the whole, probably the most convenient and practical guide we have at present to the recent revolutionary psychiatry.

INTRODUCTION TO INFECTIOUS AND PARASITIC DISEASES, Including Their Cause and Manner of Transmission. By MILLARD LANGFELD, A.B., M.B. (Johns Hopkins), Professor of Bacteriology and Clinical Medicine, John A. Creighton Medical College, Omaha; Visiting Physician, St. Joseph's and Douglas County Hospitals, and Bacteriologist, the Omaha City Board of Health. With an Introduction by LEWELLYS F. BARKER, Professor of Medicine at the Johns Hopkins University. With thirty-three illustrations. Philadelphia: P. Blakiston's Son & Co., 1907.

THIS book is practically an introduction to bacteriology for the lay reader who is interested in the present day problems of health and disease. At the same time it deals clearly and concisely with the important subjects that lie on the border lines of pathology, bacteriology, practice, and hygiene. There are nine chapters, dealing with: Causes of Disease, Bacteriology, Phenomena of Infection, Inflammation, Animal Parasites, Avenues of Exit of Infectious Agents and Parasites from the Body, Portals of Entry of Infectious Agents and Parasites into the Body, Portals of Entry and Avenues of Exit of Microorganisms in the Various Diseases, Disinfectants and Disinfection, Collection and Examination of Secretions and Excretions. Though the book was written primarily for nurses, second and third year medical students will find it a valuable guide and introduction to larger works. The volume is characterized by simplicity and accuracy; and the student who masters it will find that he has gained much useful knowledge, with nothing that he will subsequently have to unlearn.

ORGANIC AND FUNCTIONAL NERVOUS DISEASES. By M. ALLEN STARR, M.D., Ph.D., LL.D., Sc.D., Professor of Neurology, College of Physicians and Surgeons, the Medical Department of Columbia University in the City of New York; Consulting Neurologist to the Presbyterian and St. Vincent's Hospitals, St. Mary's Free Hospital for Children, and to the New York Eye and Ear Infirmary, etc. Second Edition, Thoroughly Revised. Illustrated with 282 Engravings in the text and 26 plates in colors and monochrome. New York and Philadelphia: Lea Brothers & Co., 1907.

IN its present edition Professor Starr's authoritative treatise has undergone much amplification not only in the original matter, but more particularly in the addition of an entire new section devoted to the functional nervous diseases, so that now the volume covers the whole field of neurology, both organic and functional. The author's wide experience, both as clinician and teacher, has been utilized to the full in his presentation of the subject matter, so that a notable characteristic of the work is the true originality and freshness that it has acquired through being founded so largely on personal observation and research. The introductory chapter on the structure of the nervous system should prove especially useful to the average reader, for this subject has reached a stage of such complexity and is hedged about by so many conflicting views that only a specialist is capable of weighing the evidence presented by the different investigators, and a critical and lucid explanation of the present status of our knowledge is a highly desirable acquisition. Another noteworthy portion of the work is that containing the chapters on cerebral abscesses and tumors, which gains particular practical value through the careful discussions of the indications for surgical intervention and the methods of localization in such cases, a field in which the author's preeminence is undoubted. The new section on the functional diseases comprises the spasmodic neuroses, epilepsy, paralysis agitans and tremor, tetany, neurasthenia and the occupation neuroses, hysteria, and migraine.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-fifth Annual Meeting, Held at Exeter, July 27 to August 2, 1907.

PRESIDENT, RICHARD ANDREWS REEVE, B.A., M.D., LL.D., TORONTO.

PRESIDENT-ELECT, HENRY DAVY, M.D., F.R.C.P., EXETER.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 288.*)

SECTION OF SURGERY.

Wednesday, July 31—First Day.

GEORGE A. WRIGHT, F.R.C.S., MANCHESTER, IN THE CHAIR.

The Relative Value of Inhalation and Injection Methods of Inducing Anesthesia.—Mr. H. P. DEAN opened this discussion. His chief point in favor of spinal anesthesia was the avoidance of shock, and of the deleterious effects of chloroform and ether upon the respiratory and other organs. The inhalation method involved an affection of the highest centers primarily, and certainly did not obviate shock, or even materially diminish it. By lumbar injection the passage of vicious stimuli was prevented and all undesirable secondary effects could be avoided. Apart from shock, there was no absolute indication for the spinal method; it was hardly more than a matter of sentiment. He was guided, as to the removal of cerebrospinal fluid, by the tension discovered; when this was high he permitted the escape of a syringeful, when it was low he injected a syringeful of normal saline before the anesthetic drug. When acute inflammatory conditions of the peritoneal organs had to be dealt with, he considered the spinal the method of election.

In the discussion which followed it was noticeable that the surgeons, without exception, were favorable to the spinal method, whilst the anesthetists, though not altogether inimical to its restricted use, were, nevertheless, of the opinion that, in the hands of competent administrators, the dangers and disadvantages of chloroform and ether could be reduced to so insignificant a minimum as to restrict the legitimate field of lumbar injection very severely.

Mr. LEEDHAM GREEN recommended spinal injection as a routine procedure for all operations below the level of the umbilicus. For those in the upper abdomen it was not so satisfactory, unless combined with the hypodermic administration of morphine or scopolamine and morphine. Adrenalin he considered a dangerous addition. As direct indications he considered respiratory disease, chronic alcoholism, nephritis, and probably diabetes; contraindications were childhood, the neurotic temperament, and severe septic conditions, especially of the skin.

Dr. RODMAN of Philadelphia endorsed these views, but thought there should be some special indication for the selection of the lumbar method. He had not himself observed any ill effects from the use of the method, but admitted the existence of dangers.

Mr. C. RYALL said that though there was some difference of opinion as to the selection of the drug, there seemed to be pretty general agreement as to the technique and the management of the patient.

Indications for Prostatectomy.—Mr. PARDOE read a paper on this subject. In the first place he insisted that the operation for malignant disease was not enucleation, but a free excision. Unhappily, the diagnosis was rarely made early enough for a cure to be possible. Setting aside all chronic inflammatory conditions, it was important to discriminate between the various forms of senile enlargement and to this end digital examination of the organ should be systematic and thorough. The shape, size, outline, consistency, mobility, and the persistence, or not, of the interlobar sulcus must all be noted. In carcinoma the mobility was lost, the outline was irregular, the surface was "lumpy," the gland was stony hard except in the late stages, the enlargement was slow, generally of moderate degree, but might be very great; the interlobar sulcus was lost. In adenoma, on the other hand, the gland, though lobulated, was smooth, it was soft and elastic, might be small or enormous, and the sulcus persisted; fibroma was small and hard, regular and rounded; mobility persisted. As regarded treatment, the suprapubic route was undoubtedly the operation for all adenomata, but for fibromata the perineal route might be selected and removal piecemeal employed, or a mèdian prostatectomy might be performed. Whilst the operation of expediency, with cure as its objective, could be performed only before the onset of cystitis or the effects of back pressure upon the kidneys, the operation of urgency should not be refused even to patients seriously infected, although in them it was advisable to drain the bladder suprapubically for a week or ten days before the actual enucleation.

Mr. P. I. FREYER described his latest series of 107 cases of prostatectomy for adenoma, including one in which the organ weighed 11¼ ounces. He remarked upon the frequency of cancer of the organ, and stated that hemorrhage was a very rare symptom of the condition. His criteria for diagnosis did not differ in any essential particular from those indicated by Pardoe, but he suggested that the existence of small nodules in a seemingly adenomatous gland should always arouse suspicion of malignancy. The mortality from all causes in his 432 cases amounted to 7 per cent.

Thursday, August 1—Second Day.

Indications for Cholecystectomy.—Mr. J. BLAND-SUTTON, in opening this discussion, pointed out that neither physiology nor comparative anatomy could furnish evidence of any indispensable function for the gall-bladder, while pathology and clinical experience alike indicated the serious menace of the disease conditions to which it was so prone. The best way of treating these conditions was to excise the gall-bladder with as little compunction as surgeons felt in removing the vermiform appendix. Cholecystectomy was indicated for (1) injury, (2) calculous cholecystitis, (3) acute noncalculous cholecystitis, (4) perforating ulcers, (5) mucocele, (6) empyema, (7) fistula, (8) malignant disease. Submitting that cholecystectomy should be adopted as a routine procedure, Mr. Bland-Sutton expressed his belief that the results attained fully justified his position, only claiming that in compiling statistics similar divisions should be used, as was the custom in dealing with the appendix, viz., the acute, perforative, and gangrenous cases should be considered separately from those of simple cholelithiasis, and that the malignant cases should be classed by themselves.

Mr. MAYLARD objected to the comparison between the gall-bladder and the appendix, thinking that the element of intermittency of flow of bile, to which the storage function of the gall bladder contributed, was one not to be regarded lightly; moreover, the continuous drainage secured by cholecystotomy was of undoubted advantage. As regarded the operation, safe and simple as it might be, there was more danger of a weak cicatrix where it was necessary to resort to packing the bottom of a deep wound.

Mr. CHARTERS SYMONDS, reviewing his operative experience for the last five or six years, said that his tendency had been towards the more frequent removal of the gall-bladder; at the same time a choice of operation was often a matter of great importance; in cases of simple cholelithiasis he saw no obection to cholecystotomy, since it was generally possible to anticipate from the condition of the parts those cases in which such sequelæ as fistula or suppuration were likely to occur; he would reserve excision for these. It was not sufficient to consider only the pathological state of the gall-bladder itself in deciding which procedure to adopt; the general condition of the patient, and particularly the question of jaundice, must rank as an essential factor.

Mr. STANMORE BISHOP, while agreeing that most of the

indications given by Mr. Bland-Sutton were correct, demurred emphatically to routine removal of the organ merely because it was the seat of gallstones which had produced biliary colic. The underlying catarrhal condition of the whole biliary mucosa was much more efficiently treated by drainage. In view of the possible supervention of stricture of the biliary channels, too, it was desirable to preserve the gall-bladder, which afforded the readiest means of providing an alternative route for the passage of the bile.

Mr. J. D. Malcolm thought that a judgment should be made upon the condition of the main ducts and the probability of further trouble arising in them, for which it might be of great importance to have the gall-bladder left as a means of access. In cases of disorganization of the gall-bladder by prolonged or intense inflammation, it was generally wiser to remove it, even if, for greater safety and rapidity of operating during the acute stage, the procedure were carried out in two stages.

Mr. Ward Cousins said there should be no hesitation in removing the organ when structurally diseased, provided the common duct was clear; nevertheless, when it was possible to cure the condition found by any method short of removal, he considered it advisable to preserve the gall-bladder.

Mr. Sinclair White, speaking from an operative experience of 158 cases of cholecystotomy during the last eight years, considered that excision was both unnecessary and more dangerous than simple drainage, especially in cases where acute sepsis was present.

Mr. Newbolt agreed with the last speaker, and expressed the opinion that the routine adoption of excision would result in an increase of operative mortality.

Dr. J. H. Cameron of Montreal reminded the speakers that Mr. Bland-Sutton's position was exactly that assumed twenty-five years ago by Mr. Lawson Tait, and he predicted that the passage of another quarter of a century would find a verdict passed upon the latter similar to that which the opinion of most surgeons had found against the former's advocacy of routine excision. The numerous cases associated with cholangitis and pancreatitis could be treated satisfactorily only by retention of the gall-bladder.

Dr. Rodman of Philadelphia expressed his general agreement with Mr. Bland-Sutton, except in the case of simple cholelithiasis and mucocele. The importance of demonstrating the patency of the common duct before excision could not be insisted upon too strenuously, and undoubtedly accompanying subacute and chronic pancreatitis called for cholecystostomy rather than for excision. The objections which might be urged against simple drainage were, in his opinion, much exaggerated and were the faults, not of the operation, but of errors in technique.

Intestinal Obstruction.—Mr. William Taylor read this paper. Notwithstanding the diminution in the operative mortality of abdominal operations in general, it was a lamentable fact that in the case of acute obstruction the percentage of fatal results remained at a figure that was a disgrace to surgery. For the most part this was due to the loss of valuable time at the commencement of the affection, occasioned by futile attempts at cure by drugs or by incompetent diagnosis. Among 35 recent cases there were 9 of intussusception (one in an adult), and all those operated on within twenty-four hours of onset recovered. Twelve of the 35 were due to cancer of some part of the colon, 2 to Richter's hernia, 3 to strangulation by a Meckel's diverticulum, and 5 by bands, 1 at the margins of an opening in the great omentum, and 3 were due to acute "angulation." The author recommended the use of local anesthesia for those cases which were first seen when distention was extreme and accompanied by other signs of acute toxemia. In cases of less severity he considered that it was of the greatest importance to empty the gut of its contents; to this end he had made use of an opening high up in the jejunum, from which he washed through the whole contents with a stream of saline solution to another opening a foot or so above the obstruction; on the whole, however, he advocated Moynihan's method of passing a glass tube upward along the lumen of the gut and then threading coil after coil upon it and emptying them as they were reached. He placed the present mortality at about 40 per cent., but thought it might be greatly reduced by early diagnosis and early operation.

Lesions in the Sigmoid Flexure as a Cause of Chronic Colitis.—Mr. Lockhart Mummery, in this paper, said the lesions found in the sigmoid portion of the colon were of importance to the diagnostician because they could be viewed directly with the sigmoidoscope, an instrument the use of which was attended by no danger whatever. The inflammatory lesions found might be described as simple, granular, hypertrophic, vascular, and ulcerative. In a series of 36 cases of chronic colitis, such lesions were present in 24, and of these 7 were definitely ulcerated. Seven cases were found to be due to new growth, and it was noteworthy that the symptoms in these cases did not differ materially from those of inflammatory origin. Bleeding might not occur when there was a growth, and on the other hand it often occurred when there was none. Another cause of great importance was adhesions binding down or constricting the sigmoid colon. A very great mistake was made in treating these cases on milk diet; they needed feeding up, and could take a full diet well; plenty of fat should be added. Local treatment should be by irrigation in the semiprone position; appendicostomy might be advisable in a few instances.

Dr. Garrett Anderson described a successful case of removal of a sarcoma of the lower end of the ileum; a small round-celled tumor involving the submucous and muscular coats of the gut throughout the entire circumference for five inches. A few mesenteric glands were affected.

Cervical Cysts.—Mr. G. H. Edington read this communication. Besides cases of dermoid, sebaceous, and hydatid cysts, three instances of branchial fistula were described, in which the definite relations of the tracks to the posterior belly of the digastric, and to the great cornu of the hyoid, and their termination behind the upper part of the tonsil, made it certain that they originated in the second visceral cleft. Complete extirpation was the treatment recommended.

Curvilinear Abdominal Incisions.—Mr. Maylard, in this paper, said that to reach the pelvic organs no incision gave such good access as one which traversed both recti, in a curve from one side to the other. The justification for this and transverse or oblique incisions in other parts of the anterolateral region was to be found in the anatomy of the parts, for not only was the blood supply to the edges of the wound better than was the case in the linea alba, and the lymphatic drainage more perfect, but the tension was certainly no greater when the muscular fibers were split in their course; even in the case of the rectus, a transverse wound did not tend to gape because the fibers of the sheath ran in the direction of the wound, and only one interlinear space was affected. Such wounds took a little longer to suture and therefore should not be employed in those acute conditions which imperatively demanded speed.

A New Operation for Mobile Kidney.—Mr. Stanmore Bishop described this operation. Longyear and Newman, he said, had shown that the attachment of the ligamentum suspensorium renis was, at the lower end, to the posterior muscle-band of the colon, and that it was subject to a downward pull on the right side. The operation, which was performed by the transperitoneal

route, consisted in turning down a flap of renal capsule and fixing the kidney by means of sutures traversing this flap and the whole posterior abdominal wall. One great advantage was that the exact degree of descent of the organ could be estimated from the direction of the renal vessels, and rectified with perfect precision.

The Saccular Theory of Hernia.—Mr. R. W. Murray read a paper based upon the results of 200 consecutive necropsies made upon persons in whom there was no history or evidence of hernia. Potential sacs were found in 47 of the bodies; 30 males of average age of 47½ years presented 1 umbilical, 11 inguinal, and 34 femoral sacs; 17 females showed 2 umbilical, 2 inguinal, and 18 femoral sacs; that is, 68 peritoneal diverticula were present in 47 individuals who had not suffered from hernia in life. The bearing of the evidence thus adduced as to the predominant influences of an existing sac in the production of rupture, upon treatment, would be to emphasize the importance of obliterating the sac.

A New Operation for Hemorrhoids.—Mr. A. H. Vernon described this operation. The bowel was occluded with a metal plug which was traversed at the lower end by two channels at right angles; through these two harelip pins, entered about an inch from the mucous margin, were passed, and beneath them was wound a length of rubber tubing. In this way the piles were made to protrude considerably, and could be removed in their entirety without any bleeding. The procedure was cleanly, rapid, and sure.

Mr. Ward Cousins related the history of a case of large composite odontoma.

SECTION OF OBSTETRICS AND GYNECOLOGY.

Wednesday, July 31—First Day.

Ernest Hastings Tweedy, F.R.C.P.Ire., Dublin, in the Chair.

The Justification for Artificial Dilatation of the Cervix to Hasten Delivery at Full Time, and the Most Appropriate Method for Procuring this Dilatation.—Dr. Robert Jardine opened a discussion on this subject. He said that the procedure was justified by use and wont; also because by the performance of the operation in certain cases the mother's life could be saved; in other cases it was necessary in the interest of the child. Among the methods of performance of the operation he mentioned: (1) Those which were somewhat approximated to the natural process—first, by the use of hydrostatic bags of the type of Barnes's or Champetier de Ribes's; secondly, the vaginal tampon, which stimulated uterine action; (2) More rapid methods by stretching the canal—first, the manual method; secondly, the bimanual method; thirdly, the use of screw dilators of the type of Bossi's; (3) Cutting methods—first, multiple incisions when the cervix was taken up; secondly, vaginal cesarean section, when the cervix was not taken up. Considering these latter separately, he said that manual dilatation was the oldest method and the one most usually adopted. First one finger was inserted, then two, then all the fingers and the thumb; this method was very effectual with a soft and yielding cervix; a hot douche during the operation assisted the process, and when the cervix was sufficiently low down both hands might be used. This was a most useful method, but the hand must be aseptic. The advantage of it was that the cervix could be examined during the process and any tearing could be detected at once. Bossi's dilator, unlike the fingers, gave no information of tearing. With it the dilatation should be done slowly, half a turn being made at a time, and the proceeding should take at least half an hour. It was not so much used now as a few years ago. In the hands of a rash man, it was an instrument of destruction. Incisions should not be resorted to unless the cervix was taken up, but it was not essential to have an engagement of the presenting part. Two to three, or sometimes six or seven, incisions were required. Lateral incisions, if enlarged by tearing, might lay open the uterine arteries, and therefore he would avoid making them exactly at the side. The child should be immediately extracted by forceps and the incisions stitched if any bleeding occurred. Vaginal incisions might also be required. The placenta should be quickly expressed or extracted manually. The risks were injuries to maternal parts, especially the bladder, hemorrhage, and sepsis. One should be ready to tampon if necessary. In deciding which operation to resort to, if one was not expert he should avoid vaginal cesarean section. If the cervix was soft manual dilatation should be chosen. In cases of placenta prævia he advised vaginal plugging and the use of Champetier de Ribes's bag. Screw dilatation was not good in these cases, as the cervix was soft and easily torn. The speaker did not approve vaginal or cesarean section in cases of rigidity of the cervix.

Professor Strassmann of Berlin said that in Germany the rubber bags were considered best for practitioners, as they involved no danger of injuring the womb. He had known of four or five cases in which the uterus was torn up into the body, with a fatal result, by the use of Bossi's dilator. He plugged the cervix with iodoform gauze, and when speed was necessary he used deep incisions; this was particularly the case in eclampsia. Vaginal cesarean section was not applicable in a private house, but was the best procedure in a hospital. He used the rubber bags with a one-pound weight attached.

Dr. Galabin of London said that manual dilatation had many advantages. He had met with cases in which slow dilatation of the os was due to undue adhesion of membranes around it, and he treated these by passing in a finger and detaching the accessible portion of the membranes. He thought the Champetier bag better than the Barnes bag. In early stages of dilatation Bossi's instrument was useful, and in later stages Champetier's bag. Vaginal cesarean section was limited to skilled operators, and was particularly called for in primiparas where the cervical canal was not yet taken up.

Dr. Munro Kerr of Glasgow said that if accouchement forcé was done in the interest of child delivery it must be rapid, and we could only consider forcible dilatation or incision. If it were to be done in the interest of the mother, slower methods were preferable. Vaginal cesarean section was the most dangerous of all the methods, and he had injured the bladder in performing it.

Dr. Edge of Wolverhampton said Bossi's dilator caused dangerous tearing. He had known a case in which the uterine artery was torn across; no hemorrhage occurred while the cervix was drawn down, but began as soon as it was released.

Dr. Inglis Parsons of London preferred abdominal to vaginal cesarean section.

Dr. S. Cameron of Glasgow had used the Bossi dilator in twelve cases of eclampsia, but thought it was bad in cases of accidental hemorrhage.

Dr. R. J. Johnston of Belfast drew attention to the large number of cases in which laceration occurred in natural delivery.

Dr. Purslow of Birmingham advised the use of rubber operating gloves in performing manual dilatation.

Dr. Semple of Toronto, Canada, said that practice in Canada was in favor of exercising patience before proceeding to violent methods, and he thought that incisions of the cervix were not often necessary in ordinary practice. He agreed with a previous speaker who had said that adhesion of the membranes was sometimes a cause of rigidity.

Dr. Thomas Wilson of Birmingham said he still used laminaria tents to effect dilatation of the cervix. He had found vaginal cesarean section to give satisfactory results in appropriate cases.

Dr. SWAYNE of Bristol used the Bossi bags or preliminary dilatation, but thought that serious lacerations might be caused in the later stages. He would not use the Bossi in cases of pathological rigidity of the cervix.

Professor DIXON of Cambridge had made investigations on extract of the placenta, and had obtained a substance which, when administered to animals, caused uterine contractions and dilatation of the cervix. He thought that further investigation might succeed in producing a substance which could be used clinically for this purpose.

THE PRESIDENT, Mr. E. H. TWEEDY, said that the discussion had called out the opinion that dilatation of the cervix at full term was sometimes called for. A woman should not be allowed to die with a child in her uterus. The speaker was, however, reluctant to dilate the cervix for any form of hemorrhage.

Dr. JARDINE, in closing, said that he quite agreed with those who held that dilatation was not an operation which should be lightly undertaken. In making dilatation with the Bossi bag one should always feel the cervix with the finger.

Chorion Epithelioma.—Dr. SWAYNE of Bristol read this paper and reported two cases which had been under his own care, and discussed the question of operating in the face of physical signs pointing to metastases in the lungs, stating that these should not be regarded as an absolute contraindication, as several cases had been published in which such physical signs had disappeared after removal of the primary growth by hysterectomy.

In the discussion on this paper, Professor STRASSMANN of Berlin suggested that cases of hydatid mole should be examined at intervals afterwards in the same way as cases of cancer which had been submitted to operation were examined for signs of recurrence. Two cases of chorion epithelioma in male testicle had been reported.

Dr. THOMAS WILSON said the condition was by no means a rare one, and there had been five cases at the General Hospital, Birmingham. Evidence of metastatic growth in lungs was not an absolute contraindication to operation.

Dr. MUNRO KERR of Glasgow had found chorion epithelioma followed hydatid mole in a very small percentage of cases, but thought subsequent examination very necessary.

Dr. EDGE said he would remove vaginal wall, as that was a frequent seat of secondary growths.

Dr. F. J. MCCANN thought the prognosis of operation was worse than in other malignant growths.

Dr. SMALLWOOD SAVAGE of Birmingham narrated a case.

THE PRESIDENT said that it was important to diagnose hydatid mole at an early stage, before cysts were expelled.

Thursday, August 1—Second Day.

Measures to be Recommended to Secure the Earlier Recognition of Uterine Cancer.—Professor H. R. SPENCER of London said that more women died of cancer of the uterus than from that of any other organ of the body. This was shown by statistics of the Registrar General. The highest mortality occurred between the ages of forty-five and fifty-five, and the deaths amounted to 4,000 annually. In the early stages it was curable in a large proportion of cases, and the most desirable object was to get the cases early. One difficulty in doing this was the pessimism of some distinguished gynecologists. Thus Baldy of Philadelphia said "the results were terrible;" Pozzi said "definitive cures were not yet proved," and several others spoke in a similar strain. This did much harm. It was difficult to explain these unfortunate results, which were refuted by those obtained by other authorities, some of whom showed one-third of the cases cured, when the disease was limited to the uterus. His own records showed 24 per cent. of cases well five years after vaginal hysterectomy. Several cases had been published in which there was no recurrence at the end of twenty years. Cancer of the body was not so liable to recur as cancer of the cervix. The percentage of operability was variously stated by different authorities, whose figures varied from 6 to 92 per cent. In his opinion 25 per cent. were operable; the percentage of operability was increased by Wertheim's operation to 45. He would limit Wertheim's operation to advanced cases, as in the earlier cases he had obtained better results from vaginal hysterectomy. The reasons why so small a proportion of cases came early were (1) patients' ignorance, (2) doctor's neglect to examine, (3) patients' objection to examination. The patients regarded all hemorrhage at or after the menopause as normal, whereas in the great majority of cases hemorrhage after the climacteric was due to cancer. The general practitioner was sometimes at fault; he should advise an examination in all cases of suspicious hemorrhage, and an action at law might lie against a medical man who neglected to do so. In Germany the public press was used to advise women on this point, but he did not think that would be advisable in this country; however, the attention of nurses and midwives should be drawn to the early symptoms. He appealed to all medical men to examine by finger, speculum, and by removing a piece for microscopical examination in doubtful cases. Friability of the tissue was an important symptom. A small piece should be cut out, including healthy tissue, when a microscopical examination was to be made. In cases in which cancer of the body was suspected the diagnosis should be completed by dilating with laminaria tents, followed by a Hegar bag, and the cavity should be explored with the finger, tissue being also removed with the curette for microscopical examination. The microscopical report should be compared with the clinical symptoms. He regarded the use of the speculum as most important, and urged that all students should be taught to use this.

Mrs. SCHARLIEB of London said that if we could make students and practitioners and nurses understand the importance of examination, many lives would be saved. Operation on cases which were too advanced had a most favorable effect in deterring suitable cases from seeking surgical aid.

Dr. GALABIN of London said cancer of the cervix occurred earlier than almost any other variety of cancer. In cancer of the fundus the diagnosis was difficult, and microscopic appearances might be misleading. Pain was an important early symptom in cancer of the fundus, but not in that of cervix. If a negative result followed microscopical examination it should be repeated. A watery discharge after the menopause was an important symptom. He had known twenty years' freedom after supravaginal amputation of cervix. He thought that local infection at the time of operation was an occasional cause of recurrence.

Professor STRASSMANN of Berlin said that in Germany 30 per cent. to 40 per cent. of cases were found to be operable and 10 per cent. to 15 per cent. were cured. He would ask every patient hte date of the appearance of symptoms. In Germany 50 per cent. were found to have been treated without examination by medical men. In Berlin leaflets were issued to doctors describing the symptoms, especially bleeding on coitus, and asking them to make an examination in all suspicious cases, and send a piece for microscopical report to a specialist. A leaflet to midwives who attend 90 per cent. of the childbirths was also issued, pointing out, among other things, that early cancer caused no pain. In his opinion early recognition was much more valuable than extensive operation.

Mr. BOWERMAN JESSETT of London said that in cases of excessive hemorrhage, when the cervix was normal and the sound caused bleeding, we should suspect cancer.

Dr. W. H. H. TATE of London pointed out the importance of making a vaginal examination in cases of abdominal fibroids, as cancer might coexist.

Dr. F. J. MCCANN of London advised the appointment of a committee to consider the question, but was entirely opposed to the sending of circulars broadcast.

Dr. INGLIS PARSONS of London had found that the pro-

portion of operability at his own hospital was 10 per cent. In his experience the disease spread more rapidly in young women.

Dr. CHARLES RYALL of London spoke of the circular which was given out at the Cancer Hospital. The conclusion of this was as follows: "Cancer is a very prevalent disease; it may occur at any age, but is most frequent between the ages of thirty and sixty; in spite of its serious nature successful results can be obtained if patients will only seek early treatment; once the disease appears it is absolutely necessary that it should be treated without loss of time; any delay may be followed by the gravest consequences, as the disease tends to spread and become too far advanced for any hope of cure; cancer may appear without any pain or impairment of health, and may even reach the incurable stage without causing much discomfort; cancer of the womb is generally associated with some discharge or bleeding; the discharge varies in character, and may be thick, watery, blood-stained or offensive; the bleeding may be small in quantity or excessive, and may occur at or between the monthly periods; any bleeding, no matter how small, which occurs at an unusual time requires investigation; unfortunately, women afflicted with serious symptoms frequently think that the latter are due to the 'change of life,' and therefore they consider them of little importance, and delay seeking early treatment; this delay is one of the causes of so many cases being incurable; if you have any suspicious symptoms seek immediate medical advice; the disease must be treated as early as possible; do not delay, as the consequences may be serious; when in doubt consult your own doctor."

Dr. THOMAS WILSON of Birmingham had found that half of his cases had not been examined by a medical man. In his lectures to midwives and nurses, he had always laid stress on the early symptoms of cancer, and he had found the ratio of operability increase from 14 per cent. to 30 per cent., partly, he thought, as a consequence of this.

Dr. MUNRO KERR of Glasgow said one great difficulty was that women who knew that something serious was the matter would not consult a medical man because they were afraid of finding out the truth.

Dr. CUTHBERT LOCKYER of London thought the greatest difficulty was the ignorance of the public.

Dr. R. J. JOHNSTONE of Belfast pointed out that in some cases cancer was found to be considerably advanced when the first symptom appeared.

Dr. EDGE of Birmingham said that it was very important in some cases to examine under anesthesia.

Dr. S. CAMERON of Glasgow advocated palliative operations when complete removal was impossible.

Dr. GILCHRIST of Lausanne said that recent investigations had shown that metabolism was altered, especially in the form of elimination of urea, long before cancer appeared, and that this fact might some day be made use of in diagnosis.

A resolution was proposed by Dr. Thomas Wilson, and seconded by Professor Spencer, that "the Council of the Association be requested to appoint a committee to consider the question of issuing instructions on the early diagnosis of uterine cancer."

Professor SPENCER, in closing, said he would not advise palliative operations. He thought that the differences in results might be explained by different methods of operating, local infection being more possible in some methods.

Friday, August 2—Third Day.

The Operative Treatment of Cervix Carcinoma.—Dr. CUTHBERT LOCKYER of London read this paper. He thought that the vaginal operation was inefficient mainly owing to the danger of implantation of the cancer cells during operation, and he had now given it up in favor of the abdominal operation. Out of fourteen cases in which the vaginal operation had been performed, only four could be traced as free from disease. Wertheim's operation was the only scientific method at the present time, as it enabled the cancer to be removed without any exposure of the surface of the growth. When the glands were involved, Wertheim said that he had known no case in which there had been more than three years' freedom. Since using Wertheim's operation he had operated on 75 per cent. of the cases seen, whereas, previously, when using the vaginal method, he had only operated on 18 per cent. He did not use a gauze drain as advocated by Wertheim.

Mrs. STANLEY BOYD of London asked where recurrence took place. She had seen recurrence in the glands. Cystitis was common after these operations, and she believed that it was caused by using a gauze plug.

Mr. J. MALCOLM of London considered the Wertheim a more scientific operation than the vaginal, especially because cancerous tissue was not exposed in the wound.

Professor SPENCER of London thought that for squamous carcinoma of the portio vaginalis vaginal hysterectomy was to be preferred.

Dr. THOMAS WILSON said that statistics were unreliable because no attempt was made to differentiate between the different forms of cancer, and he would distinguish three forms, viz., cancer of the portio vaginalis, of the cervical canal, and of the body of uterus.

The PRESIDENT had done abdominal operations in all cases of uterine cancer during the last eighteen months.

Dr. LOCKYER, in closing, insisted that the great point in favor of Wertheim's operation was not that glands could be removed, but that the growth could be completely isolated during removal.

Indications for, and Methods of, Operating on Uterine Fibroids.—Professor STRASSMANN of Berlin read this paper. The indications for operation were: (1) Pressure on the bladder; (2) severe pain; (3) alteration in the heart; (4) complications of carcinoma with myoma; (5) complication of disease of appendages; (6) twisting of the pedicle; (7) necrosis and other changes in tumor. As regarded (4) there was no doubt that a carcinoma would develop in a fibroid uterus, and he thought that cancer of the body preferred a fibroid uterus, and that pressure of the fibroid on the opposite endometrium was a factor in the causation. The symptoms of cancer of the body were: Bleeding, beef-tea-colored discharge, pain which was worse in afternoon. When these symptoms occurred a diagnostic curetting was called for, and if cancer was diagnosed extirpation should be carried out. It was well known that cancer of the cervical stump may follow supravaginal hysterectomy. Carcinoma of the ovary might complicate a fibroid. No fibroid began to grow after the climacteric; therefore a tumor, forming then, was probably ovarian. The complication of a fibroid with a pyosalpinx was very dangerous and operation difficult. The twisting of the stalk in a case of fibroid was more quickly followed by necrosis than the same accident in ovarian tumors. The standpoint he took was that true indications for operation must be present, and that he would not operate merely because a woman had a fibroid. Vaginal operation was to be preferred when possible, using lateral incisions in perineum if outlet was narrow. For enucleation he preferred anterior colpotomy, making a lateral tongue-shaped flap in anterior vaginal wall; then separating bladder and opening anterior pouch of peritoneum with scissors. When the uterus was to be saved he enucleated fibroids and drained through Douglas's pouch. He had enucleated many small tumors from women who had suffered from dysmenorrhea, complete relief of this symptom following. He had removed a fibroid weighing 7 pounds by the vaginal route, and had only once after commencing operation been compelled to abandon vaginal route and open abdomen. For patients near forty years of age he preferred total extirpation to enucleation, and he would not perform enucleation during pregnancy.

Technique of Abdominal Hysterectomy.—Dr. FRED. EDGE, in this paper, said that the operator should begin by

cleaning the vagina and cervix, with the patient in the lithotomy position, and after cleansing should put an antiseptic plug in uterine cavity. The advantages of the preliminary examination under anesthesia were that one could verify the diagnosis, and could detect fibroid nodules or cancer in the cervix; infection could be avoided by changing gloves before proceeding to the abdominal incision.

Fibroid and Fibromyomatous Tumors in Unusual Sites.—Dr. S. CAMERON of Glasgow read this paper. He first dealt with ovarian fibroids. In nine cases he had found free ascitic fluid in four, and torsion of pedicle in three. He had met with fibroid tumor in the bladder, in the Fallopian tube, and in the vagina.

Dr. HERBERT SPENCER deprecated vaginal operations for large tumors on account of the difficulty of controlling hemorrhage.

Dr. W. H. H. TATE of London had found complications of the appendages occur in cases in which the fibroid was more or less impacted in the pelvis, and thought that impaction of the fibroid in the pelvis was an indication for operation, even though the present symptoms were not severe.

Dr. THOMAS WILSON had found changes in the appendages in 40 per cent. to 50 per cent. of cases of fibroids.

Dr. SMALLWOOD SAVAGE had seen a case in which a fibroid tumor of rectum was associated with uterine fibroids.

Mr. J. D. MALCOLM preferred abdominal panhysterectomy in cases of large fibroids, and thought that the advantages of leaving one ovary, now so strongly advocated, had not been proved.

THE PRESIDENT preferred the abdominal route for large tumors.

Professor STRASSMANN, in closing, agreed that impaction in the pelvis of the fibroid was a cause of tubal disease.

A Series of One Hundred Consecutive Abdominal Sections in Hospital Practice.—Dr. INGLIS PARSONS of London read this paper. There had been one death. He kept silk in carbolic acid after boiling and sutured the abdominal wall in three layers, using silkworm gut for the aponeurosis and silk for the others. He did not use drainage tubes.

Complete Rupture of the Uterus with Escape of the Fetus into the Peritoneal Cavity; Panhysterectomy; Recovery.—Dr. MUNROE KERR read this paper. He had met in all with fourteen cases of ruptured uterus; he had operated on twelve, three by plugging; all recovered; nine by hysterectomy; three recovered. He thought that where there had been much preceding manipulation plugging gave the most satisfactory results.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Twenty-fourth Annual Meeting, Held at Washington, D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. THOMAS DARLINGTON OF NEW YORK, IN THE CHAIR.

(*Concluded from page 291.*)

Thursday, May 9—Third Day.

Sanitary Conditions at Panama, Illustrated by Stereopticon Views.—Dr. J. EDWARD STUBBERT of New York gave a comparison of the healthfulness of the Nicaraguan and Panama routes, a synopsis of the sanitary conditions that existed during the French régime, percentage of death rates, a description of the different classes of laborers employed on the canal, their method of maintenance, housing, etc. Reference was made to the work done by Colonel Gorgas in Cuba. The success attained by Dr. Stubbert in Nicaragua and by Colonel Gorgas in Cuba was regarded as the foundation of the sanitary work just satisfactorily completed at Panama. A description was given of the new towns settled by the Commission along the route of the canal, of the sewage and paving done at Colon, and of the new hotels built by the Canal Company. He also touched upon the water supply now in existence, and gave a summary of the work completed, showing that yellow fever was exterminated and malarial fever under control. The paper was illustrated by sixty-six stereopticon views.

Use of Lantern Slides in Teaching Meteorology and Climatology.—Dr. GUY HINSDALE of Hot Springs, Va., showed a selection of about 55 slides from a collection of 300 or 350, made by the University of Chicago to illustrate matters connected with meteorology and climatology. It was suggested that they were invaluable in giving courses of lectures, and that by making a selection of slides there was saved the necessity of drawing all the charts, diagrams, and maps needed for instruction, and the expense was small.

Heart Clot in Pneumonia.—Dr. BEVERLEY ROBINSON of New York City considered this subject as still an undetermined question, saying that formerly its frequency was admitted both by pathologists and clinicians, and that at present pathologists consider it a very rare occurrence. Authorities on both sides were cited. Experimental pathology would seem to prove the presence of ante-mortem clots oftentimes, though they gave rise to no distinctive signs or symptoms before death. At autopsy intracardiac or other changes might render the immediate cause of death doubtful. With previously healthy heart and kidneys the patient would usually survive, if the blood were kept in a condition approximating normal. This was said to be possible by the frequent and judicious use of saline beverages. Views regarding the efficacy of ammonia internally in preventing and curing heart clot were given. The author's views upon this point were stated and the conclusions drawn that heart clots as an immediate cause of death in pneumonia are not infrequent, and that clinical experience justifies the use of ammonia to prevent and possibly cure heart clot.

Role of Vasomotor Action in the Processes of Repair.—Dr. J. MADISON TAYLOR of Philadelphia read this paper, saying that the explanation of disease and repair on a basis of plus or minus of blood had attracted workers in the field of clinical pathology from the beginning of medical thought. Difficulties were said to have existed in interpreting facts and reconciling apparent contradictions; chiefly because of conspicuous omissions in the knowledge of fundamental principles, and also because of the overestimated significance of some facts and laws, and failure to realize the potency of others. Thereapeutic resources had proven inadequate on similar grounds. It was believed by the author that much of this obscurity would cease by achieving a practical familiarity with the rôle of the vasomotor mechanisms and applying them to the interpretation of clinical relationships to the process of repair. Physiologically this was demonstrated by the teachings of Sajous in his explanations of tissue respiration, from the standpoint of the adrenal system, which constitutes the key to circulatory regulation and oxygenation. A clear conception of the rôle of these great regulative mechanisms was said to elucidate a knowledge of the action of all drugs and remedies. Hygienic regulation, empirical and inadequate, could be made more efficient by using manual treatment, scientifically, in the light of experience from workers in this line, which has been plainly indicated and on record, but too much neglected since the beginning of the Nineteenth Century.

Substernal Remittent Cardiac Squeal.—Dr. ROLAND G. CURTIN of Philadelphia presented this paper. The sound indicated by the title was described as to location and character, and the conclusion drawn that it was evanescent—one observer might hear it and another might not—thus

giving rise to disagreement; that it was not an indication of serious disease; that no treatment of it was required, and that the fact of its disassociation with any active symptoms made it of value to insurance and military examiners.

Death from Angina Pectoris.—Dr. Curtin also presented a study of fifty-nine cases of death from angina pectoris. The point of greatest interest was the fact that fourteen of this number were physicians, which tended to prove the appropriateness of the name "doctors' disease" for the condition. Statistics showed a greater number of men having angina pectoris than women, which fact was attributed to the greater mental stress undergone by men than women.

Some Manifestations of Arterial Tension.—Dr. Charles E. Quimby of New York City read this paper, the essential point of which was the mutual dependent relations of the systemic functions, *i. e.* the physiology of disease. It was claimed that there were no pathic processes; that all the activities of diseases were objectively good, and that results only might be rightly called pathic. He believed this to be an inevitable conclusion from the study of disease along biological and evolutionary lines, and that it formed the only possible basis for a logical system of medicine and rational therapeutics. Among the many strictly physiological processes recklessly branded as "pathic," none had suffered more undeserved or deeper opprobrium than "arterial tension." The purpose of the author was to deal solely with the arterial tension of vasomotor contraction, and certain apparently unrelated disease manifestations with which it was invariably associated. Cases in point were cited, and the paper was summarized as follows: (1) All physical processes are objectively good and become pathic only by their degree of failure. (2) When such failures or perversions of function reach the dignity of disease their cause is to be sought along the lines of normal physiological action, not on the basis of so-called pathology. (3) Very many such functional diseases are found to be associated with high tension, and such tension is always a precedent not a coordinate development. (4) Such tension, although the immediate cause of the functional disturbance, is never primary, and, therefore, never an ultimate cause of anything; but does point to an ultimate cause in some condition that can develop high tension without other functional disturbance. (5) High tension is always the sign of systemic activity in self-defence, and is never to receive other than emergency treatment, for its association with apparently utterly unrelated diseases shows their common dependence upon the cause of the tension itself.

The Importance of the Early Detection of Aneurysm of the Aorta.—Dr. Horace D. Arnold of Boston presented this paper, saying that the profession at present was satisfied to recognize thoracic aneurysm in an advanced stage, because that was the picture portrayed in text-books. He believed it as important to recognize aneurysm early as to recognize tuberculosis early. The early signs were given and a report of cases made, with special reference to the signs or symptoms which led to recognition of the disease.

Carcinoma of the Mediastinum Simulating Aneurysm.—Dr. Jay Perkins of Providence, R. I., read this paper, reporting the case of a miner, aged 33, who for several years had worked hard in the Klondike. He suddenly developed marked enlargement of the neck followed by dilatation of the superficial veins of the whole body, accompanied by double murmur at aorta, and later great enlargement of area of cardiac dullness, including dullness over whole of sternum, lower right chest (and before death whole right chest), and some enlargement of glands above right clavicle and in right axilla. *x* rays showing pulsating mass to left of spine at arch of aorta. At autopsy there were shown a small carcinomatous growth pressing on the superior vena cava, a large carcinomatous growth under upper part of sternum, and tuberculous infiltration of right lung. The heart and aorta were normal.

Dilatation of the Heart.—Dr. Thomas A. Claytor of Washington, D. C., discussed this subject in its relation to etiology and treatment. Loss of muscular tone was regarded as an important etiological factor. Symptoms and physical signs were considered. In treatment two cardinal principles were emphasized: (1) Lessening the amount of work; (2) increasing the power of the heart to do the work. Attention was called to the value of small doses of opium in quieting the nervous system and supporting the heart.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. Thomas D. Coleman, Augusta, Ga.; *First Vice-President,* Dr. Judson Daland, Philadelphia; *Second Vice-President,* Dr. C. Fox Gardiner, Colorado Springs; *Secretary,* Dr. Guy Hinsdale, Hot Springs, Va.; *Member of Council,* Dr. Thomas Darlington, New York.

Boston was selected as the place of the next annual meeting the time of meeting to be left with the Council.

THE WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting, Held May 13, 1907.

Dr. Leon Louria in the Chair.

A Case of Cerebral Rheumatism.—Dr. Jacob Londoner of Brooklyn read this paper. His patient was a native male, forty-nine years old, with a previous history that was negative, except for an attack of acute articular rheumatism at the age of sixteen. There was no venereal history. When he returned home from a trip to Scranton during the recent typhoid epidemic in the latter city he was taken sick, he had severe pain at the back of the neck, was constipated, and had a sense of oppression in the abdomen. Two days later he awoke and had pain in the left ankle and toes. Toward evening his left knee, elbow, and shoulder also became painful. The next day all the affected joints were swollen and tender. On the following day the corresponding joints on the right side were similarly affected, while the inflammation on the left side began to subside. The patient now had headache, stiffness of neck muscles, and tenderness upon motion of head. He soon became delirious and entered the hospital on the thirteenth day of his illness. On admission physical examination showed that he was well nourished, but pale, tongue was coated with edges and tip red, and there was an ulceration on the left side of the uvula. There was a moderate rigidity and tenderness of the neck muscles. The eyes were normal, although the retinal vessels were somewhat large; no paralysis of any face muscles; reflexes normal; no ankle clonus and no Babinsky; Kernig's symptom absent. The right knee and wrist were tender and swollen, and the right ankle was tender. The other joints were stiff. The heart and pulse were normal. The rest of the body examination was negative. The patient was delirious and talked all the time. He had hallucination and delusions and objective and subjective vertigo. Repeated daily examinations for Widal and paratyphoid were negative. Lumbar puncture was negative. Blood analysis showed a slight anemia and a leucocytosis of 15,000. Urine examinations were all negative. The temperature was not characteristic; it did not give the picture of typhoid; it ranged between 99° and 102°. During the first two weeks it ran up to 103.5 on four different occasions. The diagnosis of cerebral rheumatism was made. This disease was known to medical authorities for many years. Pribram, who gave it special study, drew the following conclusions: 1. Diffuse cerebral symptoms, without cerebral lesions, occurred in acute articular rheumatism in two forms, (a) an acute form most common at the height of the fever, or during hyperpyrexia, and

(b) the chronic form, with either a melancholic or a maniacal picture. 2. The acute cerebral symptoms might have any of the following as forerunners: A peculiar change in disposition of the patient, a disturbance of mental equilibrium, a marked insensibility of affected joints, or a high fever without cause. With or without these forerunners there usually followed a condition of sudden excitement, delirium, hallucinations, and, in many cases, coma and death. 3. Many cases ran a high temperature. In some the temperature was low. It was probable that the causes of this form of the disease were the high fever and the rheumatic toxin working hand in hand. 4. There was a resemblance between cerebral rheumatism and some of the acute infectious diseases, as hemorrhagic variola or scarlatina with high fever. Salicylic acid poisoning gave the same symptoms. 5. Alcoholics in articular rheumatism frequently got into this delirious state. In these cases additional causes were deprivation of alcohol and inanition. Cerebral rheumatism was also resembled by alcoholics in other acute febrile conditions. 6. Hysterical or epileptic persons in acute articular rheumatism often got into a state resembling cerebral rheumatism. It was difficult in these cases to make a diagnosis, which time usually cleared up. Generally it was found to be an attack of hysteria or epilepsy. The prognosis in these cases was fairly good. 7. During convalescence from an attack of acute articular rheumatism of long duration the patient might get into a melancholic or a maniacal condition. This was not a true cerebral rheumatism. It was a condition due entirely to inanition. The prognosis in these cases was good. 8. Cerebral rheumatism was not to be confounded with cases of rheumatic endocarditis where emboli or apoplexies occur or cases of true meningitis complicating acute articular rheumatism. The duration of this disease varied. It might end in a few hours or days in death, or it might last several weeks. Cerebral rheumatism occurred in two to four per cent. of all cases of articular rheumatism. It occurred more frequently in men than in women, and mostly between the ages of twenty and forty. Predisposing factors were a neurotic heredity, hysteria, and epilepsy, alcoholism in parents, uremia, and lead poisoning. As regards prognosis fifty per cent. of all cases died. Hyperpyrexia rendered prognosis bad. Treatment was symptomatic and expectant. In cases with hyperpyrexia, hydrotherapy was the best measure and saved many lives. Salicylic acid had no effect and might make symptoms worse.

Some New Methods of Treatment after Laparotomies, with Presentation of Cases.—Dr. RUSSELL S. FOWLER of Brooklyn read this paper.

The Modern Therapy of Cystitis.—Dr. MARTIN W. WARE of Manhattan read this paper. (See page 310.)

PHILADELPHIA PEDIATRIC SOCIETY.

At a stated meeting held May 14 Dr. ELEANOR C. JONES reported "The Case of an Infant with Several Congenital Deformities." There was present a condition of spina bifida, with a cavity in the spinal cord and loss of power in the lower extremities. Drs. C. F. JUDSON and R. O. CLOCK exhibited "A Case of Pericarditis" in a boy about seven years old, who had presented to-an-fro friction murmurs with great dilatation of the heart, in the sequence of symptoms of acute rheumatism. Dr. Judson exhibited also "A Case of Congenital Syphilis" in a child about nine months old, presenting thickening and deformity of the tibiæ and spindle-shaped enlargement of metacarpal bones of the hands. Improvement manifested itself under antisyphilitic treatment. Drs. NATHANIEL GILDERSLEEVE and HOWARD CHILDS CARPENTER exhibited "A Boy with Multiple Abscesses and Superficial Gangrene of the Toes Treated by Bacterial Inoculations." The patient was about ten years old, and had been underfed and otherwise neglected at home. The opsonic index was found subnormal, and marked improvement ensued on injection of vaccines obtained from an emulsion of dead streptococci. Dr. ROY BLOSSER exhibited "A Case of Lymphatic Leukemia in a Child Seven Years Old." The patient was a girl in whom enlargement of the glands in the neck appeared in the sequence of an attack of diphtheria. The hemoglobin percentage was 15, the number of erythrocytes upward of 800,000, the number of leucocytes 76,000, with 87 per cent. of small lymphocytes. Some improvement ensued on treatment with arsenic and iron. Dr. J. H. MCKEE exhibited "Two Brothers with Chronic Parenchymatous Nephritis, Upon One of Whom Edebohl's Operation Was Performed in 1904." The mother had died of nephritis, and in both of the patients the disease of the kidney followed upon an attack apparently of scarlet fever. In one both kidneys were decapsulated and marked improvement took place, although serious symptoms have again manifested themselves. Dr. J. P. CROZER GRIFFITH reported "A Case of Thymic Death," and he exhibited the enlarged heart and hypertrophied thymus glands from the patient. The child was one of nine, seven of whom had died previously, several under circumstances and presenting symptoms suggestive of lymphatism. The little patient in question was some three months old, and gradually developed cyanosis, with a fatal issue. Post-mortem examination revealed an enlarged thymus gland capable of causing pressure on the trachea and a considerably enlarged heart. Dr. HERBERT B. CARPENTER reported "Two Cases of Retropharyngeal Abscess." One occurred in a child eight years old and the other in a child about nine months old. In each instance the accumulation of pus was evacuated by incision, and prompt recovery ensued. Dr. R. O. CLOCK reported "A Case of Estivoautumnal Fever" occurring in a child two years old. The child had chills and fever, and typical parasites were obtained from the blood.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 17, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	354	147
Diphtheria	201	21
Measles	175	11
Scarlet Fever	97	5
Smallpox	..	..
Varicella	8	..
Typhoid Fever	68	13
Whooping Cough	18	18
Cerebrospinal Meningitis	5	9
Malarial Fever	.....	.....
Totals	926	224

Dr. Max Schueller.—The following facts of Dr. Schueller's medical life are from an appreciation by Dr. Bierbach in the *Illustrirte Zeitung*: On June 19 Max Schueller, M.D., Professor at the Frederick-William University in Berlin, died in that city. It is a tragic coincidence that he should have fallen a victim to the very disease to the investigation of which he had assiduously and almost exclusively devoted the last decade of his life, the tragedy being enhanced by the fact that he fully recognized the nature of his complaint and followed its development with the interest of the investigator. He entertained no doubt whatever but that he had infected himself during his research work with the cancer parasites he had discovered. He was born January 3, 1843, at Molsdorf. He studied in Jena and Leipzic and was graduated in medicine in 1869. He then visited the Vienna clinics and served as assistant physician to the City Hospital in Hanover. In the Franco-German war he acted as military surgeon and commander of the so-called Hanoverian Sanitary Detachment. After the war he practised as physician to the courts, and in 1875 adopted the academical career by becoming Hüter's assistant in Greifswald, where, in 1876, he was privileged to read academical lectures; in 1880 he was appointed adjunct professor, and two years later he visited America. In 1883 he returned and was enrolled upon the academical staff of the Berlin University as professor of surgery, a position he has held to his death. Schueller early developed those qualifications which were to map out the characteristic direction of his scientific work. First there was the pronounced surgical talent; his skill in diagnosis based upon his intimate knowledge of anatomy; the rapid delineation of the mode of operation; the steady hand; the presence of mind in sudden complications during operation. Again, there was the indomitable thirst for knowledge as to the causative pathological factors. His first important work in this connection dealt with experiments and histological researches on the origin and causes of scrofulous infections of the joints (1880); it was the nucleuus of his great success in the treatment of tuberculosis of the bones and joints. He discovered, after many laborious attempts in the laboratory, the causative factor of chronic articular rheumatism, and, independent of Koch, the tubercle bacillus. After that, however, he devoted himself to the investigation of cancer. He started from the idea that an animal or vegetable parasite must be the cause of cancerous tumors which had so far eluded demonstration for no other reason than that the microscopic and experimental examinations were made with cold cancer tumors. By avoiding this drawback he succeeded in demonstrating quite peculiar, roundish structures. These, he thought, should be classified as animal parasites, after having followed them up closely and studied their biological relations, and these he regarded as the causative factors of cancer. His theory of the parasitical nature of cancer, however, met with no general recognition among investigators, and this told heavily on him, increasing, as it did, the disappointments of his life. He awaited death composedly, and the only thing he regretted was that the enemy with whom he had battled so vigorously should not leave him time to publish his collected works on cancer parasites, the manuscript of which was already completed.

Report of a Case of Psoriasis Treated by Roentgenotherapy.—S. J. Wright describes this case. The patient was forty years old, weighing nearly two hundred pounds. The skin was fair and the eyes blue. Both personal and family histories were excellent. He had had psoriasis for twenty years, covering the trunk, limbs to feet and hands, and involving the scalp in several places. There was no sign of the disease on the hands, face, or neck above the collar. The top of the head was bald, and was becoming more so. All treatment had been in vain. The writer began radiation in October, 1904. By January, 1905, the patient was a well man, having lost eighteen pounds of flesh. There was entire freedom from itching and discomfort. In two months the hair all returned. In May a few spots again appeared, and several more treatments were given. The patient's corpulence has returned and the scalp proves refractory. The writer has had excellent success in several other cases of psoriasis of less degree and duration. Excepting in cases of advanced, active, pulmonary tuberculosis, he has never had any symptoms of toxemia in his patients. He uses tea-lead to protect the mammary and reproductive glands from the effects of the *x*-ray, and he urges the use of sunshine as an adjuvant.—*Archives of Physiological Therapy.*

Constipation and Mental Troubles.—Perpère states that there is no person afflicted with mental trouble who is not a sufferer from constipation, at least in the early and curable stage of his malady, as well as from stomach, liver, or intestinal disturbances. Even in the normal man constipation brings about torpor of the ideas, inaptitude for work, and a bad temper. It is most important in the production of neurasthenia. In many psychopathic states it aggravates the condition. This is true in epilepsy, hysteria, alcoholism, melancholia, and even in organic mental diseases it is the rule. The general paretic is constipated. In hypochondria the irritation of a full intestine causes feelings which are ascribed to other organs and causes. The abnormal sensations are improperly interpreted. Autointoxication follows constipation, with its train of bad effects. The first treatment for patients suffering from mental disease must be the relief of constipation and the maintaining of the bowels in a normal condition.—*Le Progres Medical.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service for the week ended August 16, 1907:

A CONSIDERATION OF THE CAUSES AND THE CHARACTERISTICS OF THE WEAK FOOT;

WITH REFERENCE TO THE PRINCIPLES THAT SHOULD GOVERN ITS TREATMENT.*

BY ROYAL WHITMAN, M.D.,

NEW YORK.

TWENTY years ago, when I first became interested in the weak foot as representing more particularly the less advanced type of deformity commonly called flat foot, practically nothing was known of it, at least nothing relative to what is now considered as its importance. The flat foot, popularly classed as an inheritance, and of interest because of its appearance, was of course familiar; and the painful flat foot, supposed to be caused by a direct breaking down of the arch from the overweighting of its "key-stone," and therefore usually found among the laboring classes, was mentioned casually in the text-books. It was stated that the degree of deformity might be demonstrated by an imprint of the sole, and its further progress checked by bracing it from beneath, or, as an alternative, the descent of the arch might be favored by removing the heel of the shoe, on the theory that when it was complete discomfort must cease.

Certain shoemakers undoubtedly recognized discomfort, even when unaccompanied by extreme deformity, as caused by local strain, and treated it by stiffening the leather about the arch or by thickening the inner border of the sole of the shoe, a device improved and popularized by Thomas, and, according to Marsh, a dancing master of Bath treated flat foot successfully by the methods of exercise and posture afterwards developed by Ellis in connection with his theory of the importance of the flexor longus hallucis muscle as the direct support of the arch.

The deformity of flat foot had been analyzed and described by several anatomists, admirably, for example, by Humphrey, but the dissections were of specimens of advanced deformity, which were therefore not representative of the ordinary types of weakness in which the changes in structure had not advanced to the irremediable stage, nor did these analyses indicate the treatment by which it might be relieved or prevented.

It may be stated fairly, I think, that the importance of the weak foot, the most common and the most disabling of all the postural deformities, was unsuspected. Only those cases in which pain was associated with deformity were, practically speaking, recognized, while the treatment, whether influenced or not by the various and conflicting theories of causation, was from the curative standpoint faulty in conception and ineffective in practice.*

It is of interest to contrast this with the present time, when gout and rheumatism no longer show an extraordinary predilection for the feet, when braces for flat foot are for sale even in department shops, and when the manufacture of shoes designed to protect the arch has become an important branch of the industry. This general recognition of the numerical importance of the subject by no means implies a corresponding appreciation of its causes or of its proper treatment. The usual medical prescription is the address of a brace maker, and orthopedic surgeons, even, still demonstrate the disability by imprints of the sole, apply plates or pads whose principle is direct support of the traditional arch, and consider relief of discomfort as the final test of treatment.

FIG. 1.—Normal foot protected from strain by slight adduction.

With this, as it were explanatory introduction, I propose, as I may not assume that my work is known to you, to outline the theory

*Read at a meeting of the American Orthopedic Association at Washington, May 8, 1907

*In 1899 97 cases of flat foot were treated in the orthopedic department of the Hospital for Ruptured and Crippled: 2.6 per cent. of the total number of patients. In 1906 1,219 new cases, 18.3 per cent. of the total number, were treated.

on which it has been conducted from the first, a theory which will explain discomfort without deformity and deformity without discomfort, and a treatment based on this theory, which is as applicable to prevention as to advanced distortion. In this treatment the means employed are adapted to, and are subservient to, the end in view, that end being, as far as may be, the restoration of function.

Fig. 2. The foot in the attitude of abduction (rest), showing, as compared to Fig. 1, the change in contour.

From this standpoint, the popular term flat foot is so misleading and inadequate that it has been discarded for one that calls attention primarily to impaired ability rather than to deformity, which is, in most instances, the result of disordered function.

To illustrate, one recognizes two contrasting postures of the foot, that of activity and that of inactivity. The first is exemplified by the attitude of the runner, in which the foot points directly forward so that a line projected from the center of the limb would fall over the second toe. In this attitude the weight is balanced on the center of the foot by muscular effort. The contrasting posture is that in which the individual stands at ease, the foot serving merely as a support, the muscles inactive, and the strain falling upon the ligaments.

In the attitude of activity there is a slight incurvation of the inner border of the foot and the arch is accentuated. In the attitude of inactivity the inner border of the foot bulges, the arch is lowered, and a line projected from the center of the leg will fall inside the great toe. The foot is everted, and the weight is directed toward the inner side of the sole.

Each of these attitudes, normal under proper conditions, becomes abnormal if improperly used. An abnormal persistence of the attitude of activity would be prevented by fatigue, but the abnormal persistence of the attitude of inactivity, when the foot is in active use, has no such safeguard, and as the strain is not relieved by the alternation of posture proper to activity, deformity follows, a deformity that is simply an adaptation to the abnormal function.

It has been stated that in the attitude of rest the foot is abducted or everted in its relation to the limb, but, as when supporting weight it is fixed to the floor, the relation of abduction is caused by the inward rotation of the limb upon the foot. That is, the astragalus supporting the leg sinks downward and inward upon the os calcis. Acquired flat foot, so-called, in all its grades is an abnormal persistence or an exaggeration of this attitude of abduction, the attitude of inctivity or weakness. It seems proper, therefore, to designate it as the weak foot. Such a term, although not absolutely distinctive, has an obvious advantage over flat foot, pronated foot, and the like, in calling attention to disordered function rather than to deformity, which in many instances does not become apparent until a much later stage of the progressive disability.

The theory, then, to which reference has been made may be stated as follows: The deformity of the weak foot is an abnormal persistence or exaggeration of the attitude of abduction or rest. The abduction is primary, the lowering of the arch is the secondary element. The symptoms are not due to the deformity as such, and have no proportionate relation, therefore, to its degree. They are the result of the overstrain and injury to which disordered function has exposed the foot. The changes in the muscles, ligaments, and bones that are found in cases of long standing, are secondary and incidental to the abnormal functional use. They vary, of course, with the original structure of the foot, with the injury to which it has been subjected, and with the duration of the disability.

The causes of the weak foot, therefore, must be those that favor the predisposing and simulating attitude, of which even advanced deformity is simply the exaggeration.

Fig. 3. Typical weak feet in childhood; see Fig. 1.

These predisposing causes may be divided into four classes, which are of course interdependent and often combined.

1. Congenital or acquired abnormality or weakness of structure; the support is deficient.

2. Weakness of muscles; the power is insufficient.

3. Overweight or overstrain; the burden is too great.

4. Improper attitudes that subject the foot to a mechanical disadvantage in the performance of its functions; the adjustment is imperfect.

One speaks of interdependence, since it is evident that weakness of the structure of the foot or injury, or other painful affection, will, by checking activity, indirectly weaken the muscles and induce improper postures, and that weakness of structure and weakness of the muscles are often combined, as for example in rhachitis. Finally, that the overweight or strain which induces the actual symptoms is often not an absolute overweight or strain, but relatively so, because of the mechanical disadvantage to which the foot is subjected by the improper attitudes.

It is unnecessary, even if it were possible, to enumerate all the factors, near and remote, that may predispose to the weak foot, or hasten the progression of deformity; one may begin, however, with

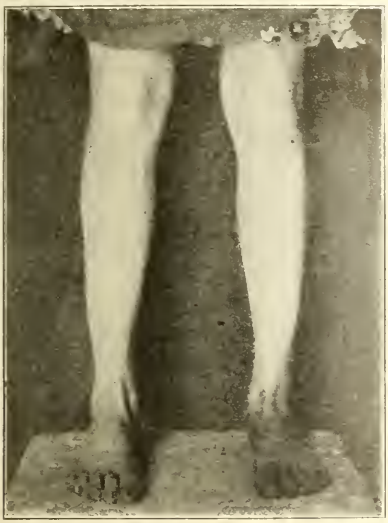

Fig. 4.—Illustrating voluntary correction of the deformity, see Fig. 3.

that which has been placed last in the table, namely, improper attitudes.

The most common of these is outward rotation of the limbs in walking. Outward rotation of the limbs, "toeing out," must not be confounded, as it usually is, with abduction or eversion of the feet which characterizes all grades of deformity.

In the first, the hip joints are concerned; in the second, the mediotarsal and subastragaloid joints. Outward rotation of the limbs is the attitude peculiar to civilized people. It is improper and ungraceful, because the feet are turned aside from the direct line of progression; consequently the strain falls upon the inner border of the foot, and the spring or lift of the calf muscle is lessened or lost. If the foot is held in the line of progression, it must be walked over, and as the front of the foot or fulcrum is longer on its inner side, the first metatarsal joint, than on its outer, the fifth, it follows that the foot is involuntarily adducted in its relation to the leg whenever the body is lifted over it; so that, when looked at from behind, the walker appears to be in-toeing at the termination of each step. Thus the weight is directed away from the inner border of the foot, the ligaments are relieved from strain, and the muscles are exercised by this normal alternation of postures.

Outward rotation of the limbs, by placing the feet at a mechanical disadvantage, by checking alternation of posture, and thus by disuse weakening the muscles, is one of the most important of the predisposing causes of the weak foot. It has probably become the walk of civilization, because the feet are so compressed and deformed by shoes that active use, which increases the pressure on painful parts, is as far as possible avoided.

Although outward rotation of the limb predisposes to abduction of the foot, which indeed is its natural sequence, the two are by no means necessarily combined. This is illustrated by the fact that in childhood in-toeing, "pigeon-toe," is one of the commonest signs of the weak foot, the in-toeing (inward rotation), which lessens the strain by compensating for the deformity (eversion), being Nature's remedy for the weakness. Many "straight" walking adults have weak feet: straight walking, therefore, by no means assures grace or strength, although it is always a safeguard against progressive disability. In this connection attention is again called to the fact that it is the persistent change in relation between the limb and the foot that characterizes the deformity of the weak foot, and that while one, to illustrate abduction, would turn the foot outward on the limb; in the standing posture, the same change in relation is caused by inward rotation of the limb upon the foot.

The soldier standing at attention illustrates outward rotation of the limbs. The same soldier, standing at ease, bearing the weight on one foot, the muscles being relaxed and the strain falling on the ligaments, illustrates abduction of the foot. In the first attitude the legs are rotated outward, and the feet are slightly abducted. In the second there is but little outward rotation of the limb, but the foot is, in its relation to it, markedly abducted; that is, the astragalus carrying the limb with it has turned inward and downward upon the os calcis, and is restrained only by the interosseous and calcaneosnavicular ligaments. In this attitude the burden is displaced inward in its relation both to the power and to the fulcrum. It is evident, therefore, why loss of spring is symptomatic of all grades of weak foot. Habitual outward rotation of the feet combined with slight abduction is characteristic of the predisposing or early stage of weak foot, while marked abduction, without outward, and with even inward rotation of the limbs, characterizes advanced deformity, the apparent degree of out-toeing being the same in each instance.

Out-toeing has been mentioned as a predisposing cause of weakness because of the abnormal persistence of the predisposing attitude and the weakness of the muscles that follows disuse of normal function. Improper shoes have been mentioned also as one of the common causes of weakness, because discomfort induces persistence of the passive attitude in walking, and because the structure of the foot is directly weakened by compression and consequent distortion. These are factors of importance in the causation of disability in persons not otherwise predisposed to it. In the same manner, by favoring disuse of the attitude of activity, local injury or gout or rheumatism, and the like, may be predisposing causes.

Direct weakness of structure may be inherited or, more commonly, it is acquired in early life, rhachitis being the most constant cause of this, as of other

similar deformities. Weakness of muscles as a predisposing cause is illustrated by the discomfort in the feet that is first noted on resuming activity after exhausting disease. Overstrain and overweight explain the relative frequency of the disability among those whose occupations require much standing and among those whose bodily weight is abnormal.

The variety of the predisposing and exciting causes explains why the symptoms of the affection may appear at any age and in any class of individuals. This is illustrated by the accompanying statistics of cases seen recently in hospital and in private practice.

STATISTICS OF 1,072 CONSECUTIVE CASES OF WEAK FOOT TREATED AT THE HOSPITAL FOR RUPTURED AND CRIPPLED

The most noticeable distinction between the two classes is the greater proportionate number of children among the private patients. It may be noted that the cases are almost equally divided between the sexes. As to the influence of sex, it would appear that women's feet are more abused by shoes, and that overweight in proportion to muscular strength is more common among them, while the influence of predisposing occupations is more marked in the male patients.

The table of age shows that no period of life is exempt from the disability, the predisposition being present, as it is probably in many instances, from childhood, the exciting cause may appear at any time.

As has been stated, the discomfort and pain characteristic of the disability are due to overfatigue and strain of the muscles; secondarily, to the accommodative changes that follow in all the tissues of the foot. In childhood, a period in which general weakness past or present is usually apparent as a predisposing factor, the principal symptoms are awkwardness and deformity. The patients are easily fatigued, and complain of discomfort in the limbs, which is often mistaken for rheumatism, but persistent local pain is not usually a prominent symptom. In adult life, on the other hand, local pain is often quite out of proportion to the deformity.

The ordinary symptoms of the weak foot, aside from the attitude and impaired function, are sensation of weakness, of tire and strain along the inner border of the foot and beneath the arch. Pain in the heels, due in great part to unrelieved pressure, is often a prominent symptom. The discomfort may be confined to the feet, but it often extends to the calves, knees, and especially in women to the back, symptoms explained by the disordered function which affects the entire body. As a further illustration of this, it may be mentioned that the weak foot in adolescents is usually accompanied by a droop of the spine (posterior curvature), which, in turn predisposes to lateral deviation. It is true that the two forms of postural deformity may be caused by general weakness, but it is probable that in many instances the general posture is a secondary result of the loss of spring elasticity and stimulation of the proper use of the feet.

The development of deformity, with its attendant symptoms, is usually very gradual, and at its beginning is characterized by a persistent attitude—that of abduction—the power of voluntary adduction being lessened by disuse and by the accommodative retraction of the opposed group of muscles. The sensation of fatigue is an indication of overstrain, while pain is symptomatic of injury, a recurrent sprain. Soon muscular spasm in the abductor muscles becomes evident. The patient complains of stiffness in the feet, of discomfort on changing from a position of rest to activity, and of pain even at night. Congestion, swelling, excessive perspiration, and other nutritive disturbances due to disordered function and inactivity, now become evident. At this stage the accommodative changes at first appearing in the muscles, then in the ligaments, now affect the interior of the joints, and the articular surfaces of the bones, changes that eventually make cure, or even restoration of symmetry, impossible.

As has been stated already, it is on specimens of advanced deformity that the dissections have been made that are supposed to represent the typical flat foot, whereas in the great majority of cases that are presented for treatment the changes have not reached the irremediable stage. It will be apparent, therefore, how important an understanding of the true nature of the disability is for its proper treatment, which implies early diagnosis, and for what is of equal importance—its prevention. Children, for example, should be properly shod, and they should be instructed in the proper manner of walking. Those who undertake laborious occupations should be instructed in the manner of protecting the feet from unrelieved strain by alternations of posture from time to time, as well as by actively cultivating the attitude opposed to deformity, and of course that which is important for prevention is also important in curative treatment.

The functional standpoint enables one also to recognize the disability in its early stages, whether it causes pain or not, and to confirm the diagnosis by the observation of the disordered function, the signs being in order of progression: (1) Persistence of the improper attitude. (2) The limitation of the range of voluntary motion in the directions opposed to the persistent attitudes. (3) Limitation of passive movements due to accommodative changes in the muscles and other tissues. (4) The evident deformity of which the important part is the abduction, the secondary element being the lowered arch. Thus, the futility of making imprints of the sole as a means of diagnosis, and their uselessness except as a record of deformity, becomes apparent.

If the foot which has become flat were well formed when the deformity began, the lateral distortion (the exaggerated abduction) representing disorganization of the mechanism must be very great, the period of progression to the position of stability must have been prolonged, and the symptoms, because of the disorganization, must have been severe and disabling. If, on the other hand, the arch were originally low, complete flatness (stability) may be acquired with but little lateral distortion, little disorganization, and with correspondingly less discomfort.

In this, as in other deformities of a similar nature,

the tendencies toward weakness often appear at a very early age. For example, as an effect of rhachitis or other form of weakness or malnutrition in which both muscles and ligaments are weak, the feet usually are flat, and as they become accommodated

Fig. 5.—Extreme adduction of the foot, illustrating the exaggeration of the arch by flexion of the fore foot over the head of the astragalus; see Fig. 6.

to, and have developed in this position from such an early period, the discomfort that attends the breaking-down process in later years is absent. Thus, one accounts for a large proportion of the painless forms of flat foot which are familiar to all.

It is of interest to note, as an illustration of the various factors that influence distortion, that although knock-knees and weak feet are often combined in childhood, yet as the child develops, if knock-knees persist, the feet in compensation for and in the effort to check the deformity become usually persistently adducted, a slight degree of talipes varus. The opposite deformity is often noted in the bow legs of older subjects, in which the feet become everted in like compensation.

In concluding this descriptive sketch of the disability, the statement may be made that all weak feet, in the sense in which the term is used here, are abducted feet. All flat feet are abducted feet, but all abducted feet are not flat feet.

One recognizes, then, as far as attitude is concerned, several classes, which are, in order of the most noticeable deformity: (1) The abducted foot; the arch is well formed. (2) The abducted and flat foot; the arch is lowered. (3) The flat and abducted foot; the foot is flat. The prognosis as to cure is favorable in the order of the classes.

In the first class one has to do simply with an improper attitude, which, when extreme and persistent, is suually a direct result of injury. In the second, the lowering of the arch indicates long duration of deformity, and, in proportion to its degree, therefore, secondary changes in the tissues. The third class includes the final effect of the two others, as well as those cases in which the arch has always been low, or was acquired at an early age, as exemplified in weak and rhachitic children. The prognosis in this class is unfavorable, because the entire structure of the foot is involved. In childhood the ligaments are lax, the muscles are weak, and years of treatment may be required for reconstruction. In the adult and adolescent class the changes secondary to deformity have, as a rule, advanced far beyond the possibility of regeneration.

It may be noted that although abduction and eversion, or adduction and inversion, movements that are always combined and carried out by the same joints, those below and in front of the astragalus are practically synonymous, there is, however, this distinction. One may invert or evert the sole to the full limit when the foot is at a right angle with the leg. Such inversion does not increase the depth of the arch appreciably, because the inner border of the foot is raised as a whole. Adduction as distinct from inversion is demonstrated when the foot is turned downward and inward to the full limit. In this attitude the forefoot is plantar-flexed and adducted over the head of the astragalus; thus, the hollow or arch is increased in depth. Similarly, the extreme limit of abduction is possible only in dorsal flexion.

Fig. 6.—Inversion of the foot, as distinct from adduction, the foot being at a right angle with the leg the arch is but slightly deepened; see Fig. 5.

The full range of adduction implies a normal articulation between the head of the astragalus and the navicular. The characteristic flat foot can be inverted, but not adducted to the normal limit, be-

cause in many instances the head of the astragalus is permanently displaced below the proper level, and flat foot, as distinct from the abducted foot in childhood, indicates an abnormal laxity of structure. This explains the division of the weak foot into classes as far as prognosis is concerned.

Fig. 7.—The best exercise for weak feet. (a) The limbs are rotated inward and the body is raised on tip-toe: see Fig. 8.

Recently, the term pronation, in common use in Germany, has been introduced to designate particularly the less advanced type of deformity, of which eversion is the prominent sign. It has no advantage over abduction or eversion, and it has the disadvantage of being unintelligible to medical students. From my point of view, it is particularly objectionable because pronation is usually understood to imply an attitude of activity, while the characteristic of the weak foot is inactivity, which both eversion and abduction signify.

So much space has been given to the consideration of the nature of the disability because the treatment is directly dependent on its proper conception. If, for example, it is admitted that the weak foot is the result of persistence of the attitude of abduction, the treatment, whether preventive or curative, will be directed toward the assumption of the opposed attitude. This will require, first, the removal of obstruction of whatever character that may limit the range of motion in any direction, and second, the cultivation of the ability of those muscles that govern it. If the mechanism is so weakened that the bones cannot be, or are not, maintained in proper relation to one another, support is essential to normal function.

If the symptoms of pain and discomfort are due to the strain upon a weakened foot, and have therefore no proportionate relation to the deformity, the relief of such symptoms which might follow simple rest is not the test of treatment. For the aim of treatment should be the restoration of normal function to the degree that is practicable in every instance.

In considering treatment one naturally proceeds from the mild to the severe types of the affection. The progress in the last twenty years has now made it unnecessary to more than mention the importance of a shoe that does not compress or deform the foot. From the first I have insisted on the importance also in treatment of a particular type, both for children and adults, that with a well-pronounced inward twist (right and left). This shape is essential, since it aids in preventing abduction. A second point of importance is to make the inner border of the sole and heel thicker, or slightly wedge-shaped, so that the foot is inclined somewhat toward inversion. This is one of the oldest of remedies, one that is continually discovered and applied by the uninstructed patient, whose shoes wear away on the inner side. The principle is applied also by the expert blacksmith, and if the shoe were firmly attached to the foot, instead of merely containing it, the expedient would be of much greater advantage in the treatment of human beings.

The patient having been properly shod must now be instructed as to attitudes. Outward rotation of the limbs must be avoided. The foot should be advanced in the line of the walk and the "springy" step should be cultivated; that is, the body should be lifted over the forefoot by exercising the calf muscle. This protects the foot from overstrain and at the same time strengthens the muscles and improves the tone of the entire body. As the prevailing attitude has been one of abduction, one now cultivates the adducted attitude; thus, in the sitting posture one should always cross the feet so that the weight resting on the outer borders should incline them inward (invert the soles).

As the adductors of the foot have been weakened by inactivity, the patient is instructed to invert the foot voluntarily over and over again. Thus, the limb being extended, the patella to the front, the foot is first plantarflexed, then turned inward, adducted, then inverted, and finally dorsiflexed to the full limit. The final exercise is most important. The patient stands erect, markedly toeing in, with the weight thrown on the outer borders of the feet. The body is then raised on tiptoe with full extension of the limbs, then is allowed to sink slowly

Fig. 8.—The body is lowered and the weight is supported on the inverted feet: see Fig. 7.

back, the feet during the descent being gradually inverted, reaching finally the extreme limit when weight is borne. The exercise, it will be noted, is exactly the same as far as attitude is concerned as that already described, with the addition of the body weight. It is therefore far more difficult. It is

A SERIES OF PHOTOGRAPHS TAKEN BY DR. W. E. GALLIE FORMERLY HOUSE SURGEON AT THE HOSPITAL FOR RUPTURED AND CRIPPLED, ILLUSTRATING THE AUTHOR'S METHOD OF MAKING THE PLASTER CAST OF THE FOOT.

FIG. 10.—The proper attitude, the foot resting upon its outer border on the inclined surface.

FIG. 11.—Applying the upper half of the mould.

FIG. 13.—The lower half of the mould.

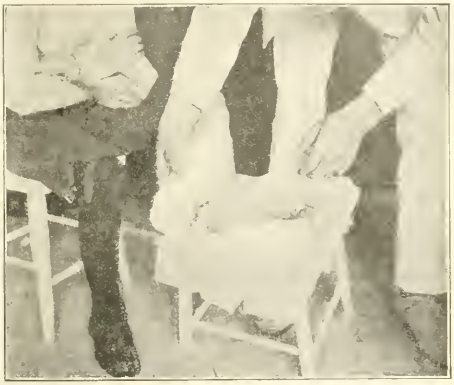

FIG. 12.—Separating the two sections of the mould.

very important, especially in the treatment of weak and awkward children, in restoring the control of the balance (curing weak ankles).

The influence of the modified shoes, the attention to posture, and the cultivation of muscular strength may be quite sufficient to cure the milder cases of disability if the cooperation of an intelligent patient is assured. In most instances, however, the tendency toward deformity has advanced so far that it cannot be controlled by the patient, and, as cure depends on reconstructive changes, in adaptation to the prevailing uses and attitudes, the importance of preventing frequent recurrence of deformity is apparent.

For this reason a brace is usually an indispensable adjunct in curative treatment. For the adjustment of such a brace an accurate plaster model of the foot in the proper attitude is essential. This is made in the following manner: The patient is seated in a chair; before him is placed another of somewhat less height, on which is placed a layer of cotton batting covered with a square of cotton cloth. Upon this the plaster mixture is poured. The foot, previously dusted with talcum powder, is then placed in the plaster, resting upon the outer border, slightly plantarflexed with the sole level, and perpendicular to the chair. It is an advantage to rest the foot on

FIG. 13.—The mould ready for the casting.

an inclined plane, the higher side toward the front of the foot, which, together with the weight of the limb, will usually assure slight adduction. For this purpose I usually use a low rocking-chair, which may be adjusted at the proper angle. By raising the

margins of the cloth the plaster is pressed against the sides of the foot to cover about two-thirds of its extent. The upper surface is then coated with vaselin, and the remainder of the foot is coated with the plaster cream. When this is firm the halves are separated, the foot is removed, and the plaster shell bound together and filled. When the model is prepared certain modifications may be made with advantage. For example, the arch is usually deepened somewhat, particularly at its posterior third, the object being to support the anterior extremity of the os calcis. If the outer border of the cast is flattened a little plaster may be added to round it slightly like the outer border of the hand, so that the brace may not press uncomfortably. If a general bulging on the inner side appears on the cast, indicating residual abduction, it may be reduced somewhat by scraping away the plaster, but if individual bones are prominent, particularly the navicular or the cuneiform, they should be marked with a pencil to indicate to the mechanic that depressions in the brace must be made for them in order that uncomfortable pressure may be avoided.

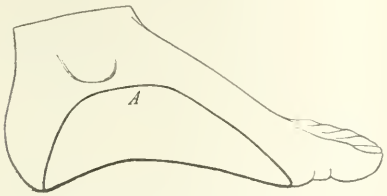

Fig. 14.—The outlines of the author's brace. *A*—the astragalus. Navicular articulation—the highest part of the arch.

On the cast the lines for the brace are then drawn, as illustrated in the diagrams. The inner margin rises above the astragalonavicular junction. The outer covers the anterior two-thirds of the os calcis and the cuboid bones enclosing this joint. The sole part of the brace extends from the bearing surface of the heel to the bearing surface of the first metatarsal bone. The front and outer two-thirds of the sole are not supported unless there are distinct indications for it, such as breaking down of the metatarsal arch. The brace is made of sheet steel, nineteen to twenty-gauge, fitted accurately, tempered, polished, and nickel-plated, or galvanized. It is simply placed in the shoe, and, as it is fitted to the foot, it finds its proper place and holds it.

This brace differs entirely in its principle from those in ordinary use. The foot is placed, as it were, in a saddle, which prevents lateral spreading and the bulging on the inner side that characterizes all grades of deformity. This positive effect is increased by the slight leverage action, for the patient wearing the adjusted shoe, and walking in the proper attitude, the outer flange first bears weight, is pressed down, and in consequence pushes the inner flange slightly against the foot at the movement of greatest strain. The sole part of the brace supports the foot, but the principal pressure often shown by thickening of the skin will be on the inner side of the foot, and there is an entire absence of the hollowed-out, atrophied appearance of the sole, which is so often present when simple, direct support is used.

The comfort and efficiency of the brace depends, of course, on the accuracy of its adjustment. Thus, if a part of the margin indents the foot it may be turned away with a wrench, and, on the other hand, if the inner flange does not clasp the foot closely, it should be turned slightly inward.

The brace may be modified in shape somewhat for special cases, and as the appearance and function of the foot improve under treatment, new casts should be made for more accurate adjustment.

I assume that at the present time it is rather in the application of the principles of treatment than in the principles themselves that I differ from my associates in this society. This is exemplified by the support which is used by many who do not understand its essential differences from those of the common type. I propose, therefore, to explain in some detail the principles of its construction and use.

If one admits that the weak foot in its inception is essentially an abnormal persistence of a normal attitude, the first indication should be the prevention of this predisposing posture. In other words, the principle of overcorrection in the cultivation of postures, and movements opposed to those which characterize the deformity, should be applied in the treatment of this as of all other similar disabilities.

The characteristic deformity of the weak foot is a persistent and often exaggerated abduction, which is always accompanied by a bulging inward below the malleolus. This is often associated with sufficient sinking of the inner border of the foot to merit the name flat foot, but when the foot is slightly adducted the bulging recedes and the depth of the arch is restored. If, then, the sunken arch is primarily an effect of attitude, an attitude first indicated by the lateral projection, a support to be effective must prevent the bulging directly, not indirectly by bracing the arch from beneath. Furthermore, sole plates, which at best are ineffective in controlling the deformity, have no influence on the attitude of the limbs, whereas the brace that has been described, if properly adjusted, controls the attitude as well as the deformity, for out-toeing, predisposing to, and even in the normal individual usually accompanied by, abduction will increase the lateral pressure to positive discomfort, a pressure that may be voluntarily relieved by the assumption of the proper posture.

As attitudes and postures are of importance only secondary to direct prevention of deformity, it follows that this brace is far superior to other supports, even if they were equally efficacious in preventing the depression of the arch, since one is a positive agent in cure, while the others are purely negative in their action. Thus far braces of comparatively unyielding material have been considered. Apparently the purpose of those who apply springs or pads of rubber, felt, and the like, is to accommodate the support to a degree of deformity at which the direct pressure on the sole can be better tolerated. I regard all sole plates of whatever character as wrong in principle. If elastic supports are more comfortable, it is because they are less efficient. No material is capable of indefinite resiliency, or, if it were, it must either permit deformity under the weight of the body or else exert abnormal pressure on the sole when weight is removed.

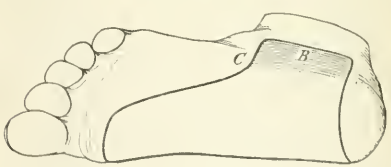

Fig. 15.—Shows the under surface of the brace and the outer flange. *B*—The calcaneocuboid articulation. *C*—The extremity of the fifth metatarsal bone.

The proper brace should hold the foot in the de-

sired position and cause discomfort if deforming postures are assumed. This can only be accomplished by lateral support which, in proportion to its efficiency, relieves the sole from pressure. It is true, doubtless, that patients may be satisfactorily treated by what seem to me ineffective supports if the other

Fig. 16.—Forcible adduction of the foot—"twisting"—the most important manipulation in the treatment of "stiff" feet.

important details of treatment are carried out. It is also true that others find relief in the ready-made braces or in stiffened shoes without supplemental treatment, or by exercises without support; that many, by accommodating their activities to the weakness, recover spontaneously, and that others with noticeable deformity suffer no apparent disability.

This supports my contention that it is the restoration of normal function—at least to that degree that may assure the patient against recurrence of disability and not the relief of the obtrusive pain which is a symptom of strain and injury, and is therefore not proportionate to the deformity or to the weakness that has induced it—which is the true test of treatment.

It will appear, then, that I do not regard a proper support as an encumbrance to be dispensed with if possible, or as an agent that supplants developmental treatment, but as one that by enforcing normal posture makes such treatment effective. Such a support is essential, therefore, in all but cases of the mildest type.

If the support is to be thus effective it must be made and adjusted in the manner described; every modification that has come to my notice, whether the result of ignorance or design, has lessened its efficiency. The most common error of those who use the proper shape is in making the plaster mould with the foot in the upright position. A cast made in this manner is from one-quarter to one-half an inch wider than when the foot is placed upon the side. A brace made on such a defective model is rather a comfortable support than one which not only restrains deformity, but enforces an attitude in which the cultivation of muscular ability can hardly be avoided.

The correctness of the principle on which the brace is constructed will be admitted, I think, the most forcible criticism being the difficulty of its adjustment. This, I thought at one time, would prevent its general adoption, but in view of the fact that it is now applied by various instrument makers with more or less success, and that between three and four hundred were applied at the Hospital for Ruptured and Crippled during the past year, I conclude that its adjustment is only relatively difficult, requiring, as contrasted with other braces, more skill or experience. It is for this reason, doubtless, that surgeons are consulted in certain instances in preference to the mechanic who makes braces or the dealer who sells them.

One is often asked how long a support of this character will be required. This question is difficult to answer, since it depends upon the age, the intelligence, and the interest of the patient, as well as upon the degree and the duration of the deformity. In the treatment of the weak, relaxed foot in early childhood, one can depend on nothing but an enforcement of attitude and the regenerative changes incidental to growth. This may require many years. In the most favorable class a period of from three to six months only is necessary, the braces being held in reserve to check the first symptoms of discomfort. In other instances the habitual use may be indicated to hold the unpleasantly deformed foot in a symmetrical attitude.

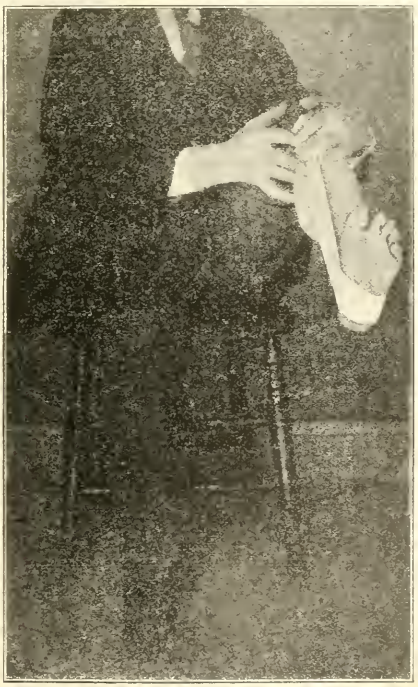

Fig. 17.—The method of applying adhesive plaster, after "twisting," to support the foot in adduction.

It has been stated that the degree of deformity has no proportionate relation to the discomfort which is the result primarily of overstrain. Consequently, when discomfort is entirely relieved, the patient usually discards supports, and often even the proper shoe. As a rule, however, the improved attitude persists, and this, with the knowledge of the

importance of the relief of overstrain, is sufficient to prevent recurrence of symptoms. At all events, it is rather unusual to again see a patient after his first discharge, if the original course of treatment has been conducted satisfactorily. I do not think, therefore, that the patient is in danger of becoming dependent on braces, a fear that is expressed by those who use the negative type.

Thus far those cases have been considered in which the secondary or accommodative changes in the tissues are not far advanced. The first change is the limitation of the ordinary movements of the foot that have been disused, particularly adduction. At first, this limitation is simply the effect of disuse, as is indicated by the fact that passive movement is unobstructed. Later there may be actual shortening of the abductor muscles and of the other tissues on the outer aspect of the foot. In most instances, however, the limitation is, in great part, due to muscular spasm, the result of the slight strain to which the foot is continually subjected during the progression of the deformity. Thus the muscular spasm and the so-called stiffness vary from day to day. At first attention is called to the resistance and discomfort only when the foot is turned quickly inward, but in the more advanced or more rapidly progressive cases the foot may be practically fixed in the attitude of abduction.

In the milder types of this class of cases one may overcome the limitation of passive motion, the first and essential step toward functional cure, by manipulation. This, what the patients call "twisting," to be effective must be carried out in the following manner, since the essentials are sufficient force and steadiness. The patient is seated in a chair; the operator, standing in front of him, places the foot (the left, for example) between his knees. The fingers of his right hand are clasped about the heel; the projection of the palm lies against the mediotarsal joint on the inner and under aspect of the foot, the hand resting on the left knee. The right hand grasps the forefoot, and, with the aid of the thigh muscles of the right limb, the foot is gently forced downward and inward over the fulcrum formed by the palm of the left hand resting on the knee. Slowly under the pressure the tense muscles give way, the movement causing, of course, more or less discomfort. When the full limit of adduction has been reached, the spasm being relaxed, the foot is moved gently up and down and from the middle line to the attitude of adduction, the patient, as far as may be, assisting. If the spasm indicating injury and strain is considerable, the attitude of adduction may be maintained in part by the use of adhesive plaster. One end of a strip about three feet long and two and a half inches in width is apposed to the outer border of the foot beneath the external malleolus. It is drawn beneath the arch and up the inner aspect of the leg to the knee, while the foot is held in inversion. It is further strengthened by strong bands about the calf, and others over the mediotarsal region and ankle, and a bandage is then applied. This method of applying adhesive plaster is not similar to that used in the treatment of a sprain of the ankle. It is used in connection with manual force to insure a progressive improvement of attitude in resistant feet preparatory to the application of a brace. The patient is also provided with the Thomas wedge on the inner border of the shoe. This treatment is continued from time to time until the spasm has sufficiently relaxed to permit the attitude proper for the brace. The patient, meanwhile by posture and by muscular effort, endeavors to improve the attitude. The treatment is especially suitable for hospital cases.

In many instances the deformity is of such long standing, or the resistance is so great, that forcible correction of the deformity under anesthesia is indicated. The steps in the process and the object in view are the same, of course, as in the manipulation that has been described. The patient having been anesthetized, the foot is forcibly moved in the various directions. The limb is then drawn over the end of the table, so that the foot may be seized between the knees in the manner described. It is then first extended and adducted, then inverted, and finally in this attitude forced upward, so that its outer border may form a right angle with the limb. This is the limit of normal dorsal flexion in this attitude. The foot is then very thickly padded between the toes and over the outer border with cotton wadding and a plaster-of-Paris bandage applied. The right-angled attitude is important in order that the patient, in walking about, may utilize the weight of the body to still further correct the foot.

It may be noted that this method of forcible correction, which has for its aim primarily the removal of all restrictions to motion and the complete reversal of the habitual attitude, is quite different from the forcible manipulation in which one attempts to directly raise or remould the arch by pressure from beneath. In the manipulation described, the foot in complete extension is pushed below the head of the astragalus, then to its inner side, and in the final dorsiflexion it lifts it to its normal attitude. Thus the arch of the foot is reconstructed.

In cases of long standing this overcorrection of deformity requires force and persistence, alternate relaxation, and pressure, a force that cannot be supplied by wrenches or other mechanical devices. In very resistant cases, division of contracted parts may be advisable, occasionally the peroneal tendons, more often the tendo Achillis; for the calf muscle, because of the everted and plantarflexed position of the os calcis, sometimes becomes structurally shortened. Such tenotomy is, of course, a mere incident to the correction of the deformity and to the recovery of the complete range of motion.

It may be noted in this connection that slight limitation of dorsal flexion is not uncommon in apparently normal individuals, explained doubtless by the use of heels. Also, as is well known, the dorsal flexors are particularly susceptible, and may be weakened temporarily by various causes permitting slight degrees of equinus, as illustrated by certain types of hollow or contracted foot. This, as well as limitation of motion in other directions, must be overcome before functional cure can be accomplished; the slight degrees by methodical stretching, the more marked forms by force under anesthesia or by tenotomy.

After forcible correction the plaster bandage is retained until all discomfort has subsided. Its object is to rest the injured part and to thoroughly overcorrect the deformity, and to enforce the new attitude upon the patient. Meanwhile the patient is encouraged to walk about, in order that the mechanism may become accustomed to the new attitude and that the weight of the body may still further stretch the contracted tissues. In from two to four weeks, according to the duration and to the degree of the deformity, the bandage is removed, in order to prepare the cast for the braces. It is then reapplied, and is worn until the shoe and the brace are ready, the aim being to prevent even temporary recurrence of deformity. Then may follow, if practicable, special treatment for the restoration of function, namely, massage, hot water, or hot air, and the like. In most instances, however, except in the rheumatic types, the patients are of the hos-

pital class, and one must depend upon the plaster strapping, and particularly the methodical "twisting" in the manner described, this being the one essential for success.

Forcible correction should not be mistaken, as it often is, for an operative treatment of flat foot. Its sole purpose is to place the patient in a position in which he may be treated for flat foot in the manner that has been described.

Time does not permit the consideration of exceptional causes or of exceptional types of deformity, or of exceptional methods of treatment that may be of service in individual cases. That which has been outlined will, if efficiently applied, meet all the conditions that one is likely to encounter.

One of my earlier papers on this subject appeared in the first volume of the *Orthopedic Transactions*, and my last was read before this Association in 1896. Further experience has broadened and confirmed, rather than materially changed, the original conception of the weak foot as essentially an abnormal persistence and exaggeration of a normal attitude. This has enabled me to recognize the early and progressive types of the disability, to demonstrate their curability by the restoration of normal function, to extend the same principle in treatment to all grades of deformity, and to devise practicable means for its application.

At the present time it is rather in these practical, and what seem to me logical, deductions than in the principles themselves that I still differ essentially from many of my associates. To place these distinctions clearly before you is the object of this, the concluding paper of the series.

A PRELIMINARY REPORT OF RESEARCH WORK ON THE EFFECTS OF TROPICAL CLIMATE ON THE WHITE RACE.*

By EDWIN P. WOLFE, M.D.,

CAPTAIN AND ASSISTANT SURGEON, U. S. ARMY.

During the summer of 1905, on account of the conflicting opinions and of the complete absence of any scientific data as to the length of time which the northern white races can safely endure the tropical climate, a series of investigations on the subject were instituted by Colonel Charles B. Byrne, Assistant Surgeon-General, U. S. A., Chief Surgeon, Philippine Division.

It was early realized that the work, to be of value, must be thorough; the examinations extensive and made at regular intervals; that it would be necessary to select a lot of men representative of the various types to be found in the service rather than to attempt to consider the whole mass of troops; that the selection should include an equal number of blondes and brunettes, of men with blue eyes and brown; that uniformity in the work was essential and that the personal equation should be eliminated as far as possible. To this end it was finally decided to make the selection from the troops last arrived in the Islands; to select two posts in each of the three departments; to examine such number as could be readily examined once in six months; to make the initial examination as soon as possible after the arrival of the troops in the Islands, and the last just prior to their departure for the United States; to repeat the examinations every six months, and to have all the examinations in each department made by the same individual so far as practicable.

In keeping the records of the examinations a special blank was found necessary, which I prepared at the request of the Chief Surgeon. It comprised as complete a record as seemed to be required, provision being made for any special feature which might arise during the course of any examination. Exact deductions of the state of the functions of the nervous, muscular, alimentary, and urinary systems could not be made from lack of time and the necessary apparatus. Blood pressure could not be determined for the same reason. Nevertheless, full use was made of all the ordinary methods of clinical diagnosis in every instance. A record of the exact location of the apex, pulse rate, and heart sounds was kept. As to the pulse rate, sufficient time was consumed in the preliminary examination to allow the individual to quiet down before it was taken.

Not only was a complete physical examination made in every case, but also a complete examination of the blood. The von Fleischl hemoglobinometer was used to determine the hemoglobin and the Thoma-Zeiss apparatus to determine the corpuscles. The hemoglobin estimations were made with each eye separately. The strip dividing the two compartments was kept in line with the vertical axis of the eye and several readings were made. These readings were then averaged and the result recorded.

In counting the leucocytes a one-third of 1 per cent. solution of glacial acetic acid in water was used as the diluent and gave very satisfactory results. Sixteen hundred to two thousand squares were counted in every instance. In counting the erythrocytes a 3 per cent. aqueous solution of sodium chloride slightly colored with methyl violet was used as the diluent and was found very satisfactory. Not less than two hundred, and for the most part four hundred, squares were counted in making the estimate. Care was also taken in mixing the blood and solution thoroughly before placing in the counting chamber.

In making the differential count Wright's stain was used and the percentages determined on the basis of a count of five hundred cells. The count was made from smears on the slide, instead of on a cover glass, and generally two or three slides were used. A specimen of fresh blood was examined in every instance to determine the condition of the erythrocytes, the appearance and motility of the leucocytes, and the presence or absence of parasites.

In all, two hundred and fourteen examinations were made by me in the routine of this work. Of these one hundred and four were from the Seventh Cavalry stationed at Camp McGrath, Batangas, twenty-two officers and eighty-two men. Of the latter, two were American Indians belonging to the Seneca tribe, and were examined for comparison. The remaining one hundred and ten were from the Thirteenth Infantry, stationed at Fort William McKinley, Rizal, twenty-five officers and eighty-five men. Of the latter seven were native Filipinos serving in the band, who were examined as controls. In this connection it may be noted that the resemblance between the American Indian and the native Filipino in color, physique, and physiognomy was very striking. In addition, blood examinations were made in four cases of amebic dysentery, in four persons who had been more than two years in the Islands, and in two others who were in their second tour in the tropics. The findings in these various classes appear in the tables herewith.

Inasmuch as these examinations were in every instance the initial examinations, no conclusions as to the effects of the climate on the individuals could

*Published by permission of the Surgeon General.

be drawn from them. Such conclusions must be left to others who make the later and final examinations. Such inferences as may be drawn from my investigations and from observations during my tour of service in the Philippines are given below.

Erythrocytes.—The number varied greatly, as will be seen from the tables. As a rule, the number was above the standard given in the text books, as will be noted from the average. No nucleated erythrocytes were seen. Slight poikilocytosis was seen in a few cases, but appeared to have no significance. Malarial parasites were demonstrated in three instances, two benign and one estivoautumnal.

Leucocytes.—1. Number. This differed materially in different persons. The specimens were taken about 9:00 A.M. and 2:00 P.M. The afternoon specimens showed a higher leucocytosis than the morning specimens. A leucocytosis of 14,300 was observed in a case of acute gonorrheal epididymo-orchitis. No increase was observed in three cases of gonorrhea which had passed the acute stage. In one or two cases a count exceeding 10,000 was made, in which there could be demonstrated in the individual no condition to account for the increase. In the four cases of amebic dysentery examined the count was 7,240, 10,700, 20,300, and 9,150 respectively. None of the four cases showed any signs of hepatic abscess.

2. Motility. In many specimens motility was observed in every type of the leucocyte. It varied in different specimens, depending upon the temperature of the room and the length of time the specimen had been taken. The lower temperatures, 75° to 85° F., inhibited the movements in the smaller forms in a very short time. In the afternoons, when the temperature of the room approached that of the body, the activity was marked and lasted for quite a long time. In the smaller cells the activity was confined to the nucleus, for the most part, but as the cells became larger the movement in the cytoplasm became more marked, reaching its greatest activity in the polymorphonuclears. Sometimes it was greatest in the neutrophiles and again in the eosinophiles. Next in order came the transitional forms, the large lymphocytes and large mononuclears, the larger of the small lymphocytes, and least of all in the smallest of the lymphocytes. Active progressive movements were observed in even the smallest of the lymphocytes in a number of instances. In this connection it may be of interest to note that the activity of the leucocyte was noticeably less in the native Filipino than in the white man under the same condition, and further, that it was greater in those white men who had been a few months only in the Islands than in those who had been there two or three years, the conditions of the examination being the same in both instances.

3. Morphology. The theory that all types of the leucocyte are but different stages in the life cycle of a single leucocyte did not appear to be borne out by the facts. The impression conveyed by this series of examinations was that the polymorphonuclears and the mononuclears belong to entirely different classes and have equally different origin. As to the neutrophiles and the eosinophiles, although the granules of the former approached those of the latter in size and staining characteristics in many instances, the similarity was never so great as to leave any doubt as to the type to which the cell belonged.

Many cells were seen which did not correspond satisfactorily with any of the classified types. This was particularly noticeable in the mononuclears. A great difference in size of different cells of the same type in the same specimen was frequently observed. For instance, eosinophiles and neutrophiles were seen which had all the characteristics of their type, and yet were not larger than the erythrocyte, while other cells of these types had two or three times the diameter of the erythrocyte.

It is believed that the so-called "transitional form" is nothing more than a large mononuclear in which the irregular nucleus is due to the arrest and fixation of the cell upon the slide rather than to a beginning division of its nucleus and transformation into the polymorphous type. So long as the preparation is sufficiently moist and warm, the cell is in active motion, the nucleus partaking equally with the cytoplasm in this activity. If now this activity be suddenly arrested and the cell fixed, as by rapid drying or hardening by chemical agents, the nucleus will remain in the position it had at the moment of fixation, and may have any shape, from a circle to a horseshoe, crescent, or the letter "S."

4. Eosinophiles. The percentage of this type varied greatly in different individuals, as will be seen from the tables. The cause of the increase could be determined in some instances, but not in the majority. In several of the individuals in whom an increase was found an examination of the feces revealed the ova of the hookworm. In one case there was a pronounced bronchial asthma. In the seven natives examined the eosinophilia was very high, intestinal parasites were demonstrated in two, and an extensive skin eruption in one. In one of the two having the intestinal parasites the eosinophilia was the lowest of the seven. One white man, in whose stools the ova of the hookworm were demonstrated in considerable numbers, had an eosinophilia of 40.6 per cent. The administration of the usual doses of thymol succeeded in dislodging only a few parasites. In his case the hemoglobin was 100 per cent., the erythrocytes 6,152,000, and the leucocytes 9,000, thereby showing no anemia, nor were there any symptoms, physical signs or indication other than those in the blood and stools, that the man had any disease whatever. No differential count was made after the administration of the thymol, consequently its effect on the eosinophile percentage is not known. This case would indicate that the eosinophile percentage cannot be taken as an index of the severity of the infection in cases of uncinariasis. Further, it is a demonstration of the fact that a diagnosis cannot be made with the microscope on one symptom alone. If this man had been suffering from diarrhea with abdominal pains, the high eosinophilia would very likely have led to a diagnosis of trichiniasis had the presence of the uncinaria been unknown or their full significance not appreciated.

The four cases of amebic dysentery, as would be expected, showed an increased eosinophilia, but not anything like that in cases of uncinariasis, being 15.4, 5.2, 6.8, and 6.8 respectively.

Motility was observed in this type of leucocyte as late as the third day after the specimen was taken. No pains were taken to keep these specimens at an even temperature. They were left in the laboratory, where the temperature varied with that of the surrounding atmosphere. The only precaution taken was to smear the edges of the cover glass with vaselin to prevent evaporation. The granules in these leucocytes had not only a gliding or flowing motion, such as would be produced by the ameboid movements, but also an independent oscillatory motion very much like that of the pigment granules in the benign malarial parasite. This oscillatory motion continued even when the cell itself was motionless. In one particular specimen this independent move-

ment was especially interesting. The cell membrane was seen to rupture and the granules to escape. They moved across the field rapidly and with sufficient force to jostle about the erythrocytes with which they came in contact. From this it would appear that these granules are provided with flagella or cilia. No stain was available with which to determine definitely the presence or absence of flagella. The nucleus in this case had divided into four irregular rounded masses. The outlines of the cell membrane could still be seen after the escape of the granules.

5. Neutrophiles. The percentage of this type varied as greatly as that of the other types. The granulation varied as much in size and staining characteristics as did the percentage. Sometimes it was very small, and again it was almost as large as that of the eosinophile.

6. Mast cells. These cells were quite diverse in their appearance. In some the nucleus was divided into three lobes, in others into two, while in a few no division could be made out. The granules were comparatively uniform in size, but their arrangement in the cell differed materially. Sometimes they were aggregated at one side of the cell, again they completely surrounded it, and at other times they were scattered indiscriminately over the entire cell. The percentage of these cells was not constant, nor was there any definite ratio between them and the eosinophiles. A high percentage did occur with an increased eosinophilia in some instances, but many specimens were seen in which the reverse was the case.

From the large number of persons found with a high eosinophilia during these examinations, in several of whose stools the ova of the hookworm were found, it is believed that uncinariasis is much more common among our soldiers and among the American people generally than is commonly supposed; that during the early stages there are no symptoms; that a differential leucocyte count is a valuable aid or indication in determining the presence or absence of uncinariasis. It is believed that a differential count made in the case of all troops returning from the Philippines would lead to the early detection and treatment of many cases of uncinariasis that would otherwise escape notice, whereby the spread of the disease would be limited. It is also believed that many of the persons found to have uncinariasis in these examinations contracted the disease before they went to the Philippines, although sufficient time had elapsed between their arrival in the Islands and the examination for the infection to have occurred and reached the stage of development manifested at the time of the examination. Uncinariasis was not found in any of the seven natives examined.

As to the effects of the climate upon the white race the following may be noted.

After arrival in the tropics, and lasting a variable period from three to perhaps twelve months, there is a state of increased activity of all the bodily functions and a sense of well-being. Following this, and lasting likewise a variable period, comes a state of quiescence or indifference which gives place insensibly to a state of lassitude, nervous irritability, muscular weakness, and neurasthenia. The skin loses its soft, ruddy hue, and acquires an anemic, muddy, yellowish-bronzed appearance, most noticeable by contrast with others recently arrived. The eyes lose their brightness and the face its alert, animated look; the conjunctiva and sclera assume a muddy-yellow hue; the elasticity and upright carriage of the body disappears; the shoulders droop; mental activity lessens and becomes more of an effort; there is a decided tendency to slouchiness in the gait and slovenliness in the dress. All these increase until finally the grasshopper becomes a burden, and nothing appears to be of importance. Then follows mental and physical stagnation and retrogression.

The life that the individual leads has much to do with the rapidity of the change. A more or less active life is as necessary for the white race in the tropics as in the temperate climates, all theories to the contrary notwithstanding. The more indolent the life the sooner the stagnation and retrogression. I have repeatedly noted that those who were active and had plenty of exercise and diversion retained their health better and their vigor longer than those who led a less active life. My attention was first called to this fact in Cuba in 1899, where the teamsters and packers, men who drank any and all kinds of water (and liquors, too), were out in the sun nearly all day, and kept all kinds of hours at night, had a very much lower sick rate than the enlisted force who did practically nothing outside of their guard duty, except lie around their tents all day, and for whom it seemed that practically every precaution was taken. There is no doubt, however, that men break down under excessive marching in the tropics quicker than in temperate climate. It is a noteworthy fact that of all the men from the Fourteenth Cavalry at Camp Overton, Mindanao, who formed a part of the provisional cavalry company in the campaign against Datto Ali in the Cotabato Valley in 1904-5, and who were out for nearly six months, not one was returned to the post for any condition which could properly be ascribed to the climate or the campaign. A few had malarial fever, several venereal disease, and one or two injuries. There was quite as much disease among those left at the post, and quite as much of it which could be ascribed to the climate, as among those on the campaign.

It is believed that the ill effects of the climate which exert themselves to the fullest extent on the nervous system are capable of a simple explanation as the results of prolonged and excessive heat.

Taking Manila and New York City for comparison, we find that the mean annual temperature of the former is 80.4° F. as against 51.9° for the latter. Not only is there a difference of 28.5° of temperature, but there is a higher percentage of moisture in Manila, being 79.4 as against New York's 73. This becomes the more significant when it is remembered that the mean minimum temperature for the three coldest months of the year at Manila is 04.5° F., which is more than twelve degrees above the mean annual temperature of New York, while during the hottest months the temperature approaches the normal body temperature for several hours a day, and often exceeds it.

In individuals accustomed to a cold climate the heat production of the body is in excess to balance the radiation and maintain the normal standard. If, now, these individuals are rapidly transported to a warmer climate, the excessive production of heat continues for a varying time, and Nature at once makes an effort to equalize the temperature by deflecting the blood to the periphery and stimulating the sweat glands, thereby promoting the elimination of the extra heat, the cooling of the blood, and through it reducing the internal temperature of the body. The persistent high temperature, and especially the humidity of the tropics, lessen radiation and the evaporation of the perspiration which retards the cooling process. This requires more time for the heat reduction, and results in a more

or less chronic engorgement of the peripheral vessels. The capillaries become dilated, and more or less stasis of the blood current follows. This engorgement of the blood-vessels interferes with the flow in the lymphatics, and the waste products are not eliminated as rapidly as they should be. It has been demonstrated that the cutaneous circulation under these conditions contains more than a third of the entire blood supply. This must of necessity deprive the internal organs, and particularly the brain, of the amount of nourishment to which they were accustomed in the colder climate. If the quantity of the cerebral circulation is diminished, the nourishment of the brain must also be diminished if this depleted condition continues.

That there is such a depleted condition of the cerebral circulation as the result of heat has been demonstrated experimentally by Schüler (*Deutsches Archiv für klinische Medicin*, XIV.), who found that when hot compresses were applied to the abdomen of trephined rabbits "the arteries and veins of the pia mater contracted, the pulsations became less pronounced and more frequent, and the respirations more shallow and rapid," and that "these manifestations were observed with more pronounced effect after immersion of the entire body in hot water, the effect being exactly in proportion to the extent of surface immersed." Immersing the body in cold water was found to have the opposite effect. The high temperature and humidity of the tropics very closely simulates the condition of the hot bath, differing only in degree.

Further, in normal conditions a continuous influence goes out from the vasomotor center in the medulla, which keeps the walls of the blood-vessels in a state of tonic activity, thereby maintaining the force of the heart, the blood pressure, and the blood distribution. Thermic, as well as mechanical, stimuli are transmitted by the sensory nerves, which have their centers in the medulla in juxtaposition with the vasomotor center and transmit impulses to it, which in the tropics result in a relaxed and dilated condition of the peripheral vessels noted above.

Schüler has also shown (*Deutsches Archiv für Medicin*, IV., 1874) that changes in the tonic excitation of the circulatory system would disturb the vasomotor equilibrium of the brain.

From this diminished blood supply to the brain there must arise a condition of malnutrition of the neurons which would manifest itself in impaired function of the various organs, particularly those under the control of the sympathetic system, reduced muscular stimulation (early fatigue), nervous and mental irritability, neuralgias, and finally mental impairment, such a train of symptoms as accompany the so-called "tropical neurasthenia" (Fales, *American Journal of the Medical Sciences*, April, 1907). As a result of the impaired stimuli to the gastrointestinal tract, the quantity and quality of the gastric and pancreatic ferments are diminished, digestion is impaired, and nutrition in general is reduced. This, in turn, results in the impairment of the quality of the blood. The brain now gets not only a diminished blood supply, but also one impaired in quality, forming a vicious cycle.

The intensity and permanency of the effect of tropical climate upon any individual depends upon his initial nerve force and the length of his stay in such climate. The more deficient the nerve force, or the more delicate its balance, the sooner will come the breakdown. The more delicate the balance and the longer the stay, the greater will be the permanency of the nervous impairment.

Some other conditions were observed in connection with the series of examinations which appear susceptible of explanation in the same manner. It will be noted from the tables that the averages for the series are as follows: Respirations, 20.5; pulse sitting, 78.7; standing, 90; exercising, 103.5; erythrocytes, 5,461,000; hemoglobin, 94.7 per cent.

It has been stated above that the mean annual temperature of Manila is 28.5° F. (or about 16° C.) above that of New York. According to the general laws of gases the density of a gas varies directly as the pressure, and inversely as the temperature, consequently the quantity of oxygen in a cubic foot of

air in Manila is only .944 as much as that of New York. $(273 + 16 = 289. \quad 273 \div 289 = 0.944.)$ Therefore, granting that the same quantity of inspired oxygen is necessary in both places, it follows that there must either be an increased lung capacity or an increased frequency of respiration in Manila as against New York. Such is believed to be the explanation of the increased frequency of respiration noted in the examinations. Likewise, there would need to be an increased oxygen-carrying power of the blood or increased rapidity of circulation, or both. The increased carrying power is found in the increase noted in the erythrocytes, which increase is present in the native as well as in the white man. It has been claimed by some that the increased number of corpuscles is due to concentration of the blood from evaporation. I was unable to disprove this theory definitely, but I believe the concentration is due to the primary stimulation of the hematopoietic centers and the resultant overproduction of corpuscles, since there is a fall in the number after a certain length of time, due to partial exhaustion of these centers. The blood count was generally lower in those who had been the longer in the Islands. It will be noted also that the average of the corpuscular hemoglobinaire is reduced rather than increased. In fact an erythrocyte count of 6,500,000 with a hemoglobin reading of 110 gives an average of 85 per cent. on the basis of 100 per cent. hemoglobin to a 5,000,000 erythrocyte count.

The increased pulse rate noted is due primarily to the thermic stimuli of the sensory nerves, transmitted to the vasomotor center in the medulla, and secondarily to the depleted condition of the visceral circulation as well as to the diminished quantity of oxygen in the air.

THE LONGEVITY OF IDIOTS.

[illegible] CLARK, M.D. [illegible] WOOD [illegible]

NEW YORK [illegible]

[illegible] belief seems common among physicians that [illegible] children rarely if ever grow to adult life. [illegible] teaching in the medical schools is no [illegible] responsible for this mistaken idea, as [illegible] pile types used in the lectures as illustrations [illegible] are almost invariably children. Most [illegible] nervous diseases illustrate chapters on idiocy, while photographs of [illegible] children, and make the general statement that idiots and imbeciles are short-lived. No official inquiry has been made into the subject, however, in idiot asylums or by bureaus of vital statistics; and, in fact, there is no literature on the subject. In former days, almshouse idiots and imbeciles were less well cared for than at the present day, and the natural reluctance of these persons to exercise predisposes them to diseases such as tuberculosis.

[illegible]

While, therefore, it is true that life is markedly curtailed in the feeble-minded and idiotic, a very considerable number live beyond even the age of forty, as shown in the graphic chart of ages at death of the last thousand cases dying at the New York City Idiot Asylum, and a second chart illustrating the ages of the seven hundred and eighty-five patients now in the service of one of us (Clark) at the Randall's Island hospitals and schools.

Tony W., aged 42 years.

Aaron S., aged 44 years.

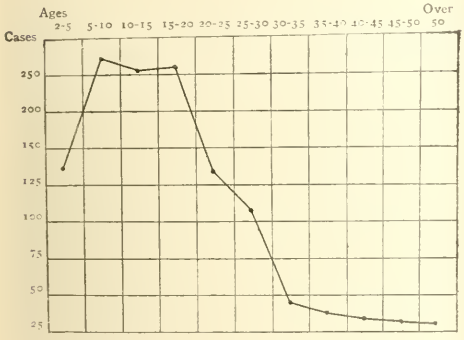

TABLE 1.—Ages at death in 1,000 cases

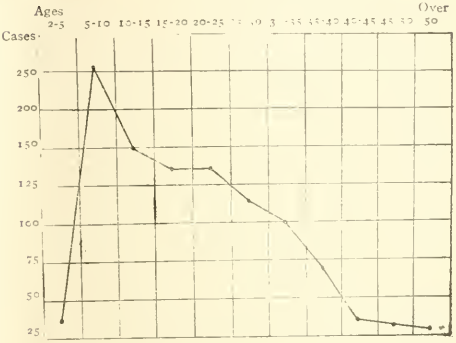

TABLE 2.—Ages of Idiots on Randall's Island.

This chart is based on the following

TABLE OF AGES AT DEATH OF 1,000 CASES.

From 2 to 5 years	115
" 5 " 10 "	221
" 10 " 15 "	204
" 15 " 20 "	217
" 20 " 25 "	110
" 25 " 30 "	80
" 30 " 35 "	23
" 35 " 40 "	13
" 40 " 45 "	8
" 45 " 50 "	5
Over 50 years	4

This table shows that while the maximum number of idiots, in the data, died under the age of twenty-five (25) years, thirty cases lived to be over thirty-five (35), seventeen over forty (40), and four over fifty (50) years of age.

The second chart is based on the following

TABLE OF AGES OF IDIOTS NOW ON RANDALL'S ISLAND.

From 2 to 5 years	14
" 5 " 10 "	201
" 10 " 15 "	125
" 15 " 20 "	111
" 20 " 25 "	111
" 25 " 30 "	88
" 30 " 35 "	73
" 35 " 40 "	41
" 40 " 60 "	21

John M., aged 40 years.

The twenty-one congenital idiots over forty years of age, in this table, were all personally examined by us and photographed by Dr. Sharp. Reproductions of four of these photographs of congenital idiots of advanced life appear in this article.

Mingled with the other cases in the table are idiots of a higher grade, some classed as feeble-minded, but all of the twenty-one cases over forty years of age are idiots of low grade. Three of these are fifty, two, fifty-four, and one is sixty years of age. Thus it may be seen that idiocy, under good custodial care, does not so seriously curtail the lives of many of these unfortunates.

From the photographs two interesting facts are at once apparent even to the novice. First, all the subjects look much older than they really are; and, second, notwithstanding that we are told that idiocy implies an absence of facial expression, we note in these illustrative photographs a remarkably increased number of facial wrinkles, the true significance of which will be analyzed at another time.

FECAL TOXEMIA.

By WILLIAM FRANCIS WAUGH, A.M., M.D.

CHICAGO, ILL.

Sometimes, when we are not sure about the pathology of a case, we form a provisional estimate of it and take this as a working hypothesis—we assume it as the true condition, and on this base our method of treatment, standing ready to make any change that the development of the case may indicate as desirable. This is in fact a duty we must defer to in very many of our clinical cases, in order that we may not lose time while awaiting the tedious processes of the laboratory. Should we wait for the Widal before instituting our treatment of a supposed typhoid fever? If we do, all that this celebrated diagnostic evidence affords us of real value is the somewhat superflous information as to what we might have done with advantage about a week previously.

No real physician does this. We form our conception of the case, and on this base a therapeusis as active as our diagnosis approximates certainty and our means of intervention allow. We may have a moral certainty as to the diagnosis of our case in its entirety. More frequently we have this certainty as to the pathological condition presenting, and we apply our therapeutics to the leading symptoms while awaiting more complete information. Since mathematical precision is so very rarely to be had in estimating deranged function, we are the more grateful that we possess something very close to such accuracy in our newer medical armamentarium. If we *know* exactly what our remedies will do, we may fit them with confidence to the presenting conditions. The comfort of such certainties must be felt to be appreciated. It is incomprehensible to the outsider. To him the confident assertions of the experienced "active-principle" practitioner must necessarily seem to be baseless, simply because he does not appreciate it.

I am contented to risk the peril of being pronounced an enthusiast, an extremist, whose theories have run away with him, in taking the position that our best working hypothesis is that of fecal autotoxemia as an all but universal principle in practice. Let me state this plainly: The functioning of the human body results in the continuous production of certain toxic elements, which are as constantly excreted from the body by the lungs, skin, kidneys, liver, etc. If this excretion is interrupted the person affected "gets sick," or even dies. A very few minutes of complete suppression of the pulmonary elimination suffices to kill. The importance of the cutaneous elimination was unsuspected until a child who had been gilded suddenly perished as a direct consequence of thus stopping the pores. Suppression of the renal output kills in some hours (Bouchard gives the exact data), while the discontinuance of hepatic and intestinal excretion after a longer time causes death, but very frequently induces illness of varying grades.

When the fecal matter lies longer in the bowels than it should decomposition goes on, and toxins are continually formed in the mass, especially in the large intestine, where the gastric acid is spent and no natural obstacle is interposed. The fluid portions, with their content of toxins, are reabsorbed and circulate in the blood. The kidneys, skin, etc., excrete these to a certain extent, and as long as they are equal to the increased task the physiological balance is maintained. If anything occurs to increase the quantity or virulence of the toxins above the power of excretion, or if the excretory function in one or more of these organs is temporarily or permanently disabled, the balance is broken and the accumulation of toxins in the blood reaches a point at which it begins to exert deleterious action somewhere.

Where will this be? At the point of lowest vital resistance—the least protected parts of the body. It may be a weak organ or nerve, one that has been the seat of former disease and is as yet imperfectly restored, its tissues loaded with débris; or one especially exposed, as the facial nerves when uncovered in a cold wind or rain. At any rate, the general toxemia is manifested by a local disorder, and, as this is frequently caused by exposure, the laity, rightly appreciating half of the pathology, say the patient has "taken cold." So he has; but we know that the trouble is due to the toxins, whose elimination has been checked by the contraction of the cutaneous surface by the cold, until they have so accumulated in the blood as to overcome the vital resistance at one point, and the ever-present microorganisms have effected a lodgment and established a colony.

How far is this principle applicable? I really do not know. The results of many years' observation convince me that it is so frequent that we may assume its presence as an element in every case, until shown to be absent. We may base on it our therapeusis, as a routine measure, standing ready to modify according to the succession of symptoms. It does not mean that there are no other elements in the etiology of disease, not by any means; but that this is an ever-present one that should always be taken into consideration and granted its full meed of importance; that unless this is attended to the other treatment is too apt to prove unavailing.

Here we have the much-derided doctrine of intestinal sepsis, the reason for the use of intestinal antiseptics, the "clean up, clean out, and keep clean" dictum. Despite opposition, derision, contempt, every method of opposition except the demonstration of its fallacy, this method has retained its place in the belief and the practice of the masses of our profession, the men who apply to theories the touchstone of actual trial. Like the doctrine of evolution, the world has passed it through the usual process, ridicule, argument, etc., and is now approaching the final stage of acceptance with enthusiasm. Gatherings of the leading specialists of the day have accepted with unanimity the dependence of lesions of the special organs like the eye, ear, throat, and nose, on autotoxemia from fecal absorption. Beginning mental aberrations have been atributed to this cause.

It is many years since Sir Lauder Brunton referred the etiology of chronic maladies of the spinal cord to this source, and we are just commencing to recognize the truth of this statement. To what other source may we, with equal chance of correctness, attribute the many chronic pathological processes in other organs? Here we have a continually acting deleterious influence, a comprehensible condition, and, happily, one under the reach of our therapeutics. We keep our eyes open for other influences, but we attend to the one constantly-present indication—to keep the bowels free.

Of course, the rabble will run away with this great truth, and the formation of the purgative habit will ensue; but we cannot lay aside a fundamental therapeutic principle on account of its liability to be abused and misapplied. It is up to us to see that this does not happen, and that we do not contribute to it by carelessly prescribing popular and easily-obtainable laxatives instead of keeping the patient under our own control.

THE EARLY RECOGNITION OF TABES DORSALIS.

By CHARLES ROSENHECK, M.D.,

NEW YORK.

NEUROLOGICAL ASSISTANT VANDERBILT CLINIC, ATTENDING PHYSICIAN TO THE METHODIST EPISCOPAL DISPENSARY.

In attempting to formulate a working basis for the early recognition of this malady, I am cognizant of the fact that the subject has been extensively reviewed by neurologists as well as clinicians, and that little or nothing original can be said regarding it; but a few timely suggestions, based on the observation of many cases seen in one of our largest neurological clinics may be of help to the general practitioner. Here I will speak particularly of the preataxic stage, when the significance of the somatic signs and subjective symptoms is still *sub judice*. With the appearance of well-defined ataxia and subjective lightning pains, the diagnosis is apparent to the veriest tyro in medicine. The laity have even learned to recognize the uncertain flopping gait and are adepts at diagnosis.

It is well to remember at the outset that for the absolute diagnosis of tabes it is not always necessary to have the classical symptoms present, viz., Argyll-Robertson pupil, lightning pains, and absent knee jerks. Any one of these signs, either fully developed or in a modified form, in conjunction with other symptoms either cutaneous or visceral, are of inestimable value for a proper conclusion. Peterson lays particular stress on the diminution or absence of knee jerks—even in the absence of any other symptom—as pathognomonic of locomotor ataxia. This inactivity of the reflexes may antedate the other classical signs by quite a long period. I have observed several such cases in which the diagnosis was ultimately strengthened by the addition of inactive pupils and lightning pains. Conversely the Argyll-Robertson pupils or pains have preceded the advent of other symptoms by a variable length of time. At the clinic we have repeatedly made a diagnosis in the presence of sluggishly-acting pupils and diminished knee jerks, and the subsequent course of the affection fully confirmed our earliest opinion.

I have made use of the term sluggish pupils. It seems quite opportune to explain the value of that sign. The ophthalmologists hesitate to commit themselves in regard to it. A pupil must be fixed, being totally irresponsive to light, before they deem it worthy of the Argyll-Robertson title; but we have learned by repeated observations that a sluggish pupil, *i.e.* one that does respond to light, but very slowly and feebly, in conjunction with any other distinctive sign, is of the greatest importance in fixing the diagnosis. I have at present under observation several such cases, which show very interestingly the development of the malady in question.

Locomotor ataxia in its incipiency appears under so many guises that it would be futile in a brief paper like this to enumerate its very earliest manifestations. I can but briefly touch upon them, and for the convenience of description and to facilitate early diagnosis will place symptoms under three divisions, viz., visceral, cutaneous, and those referable to organs of special sense.

Visceral Symptoms.—Repeated attacks of vomiting without cause in adults should arouse suspicion and cause the condition of the pupils and reflexes to be determined. Sudden bladder retention or incontinence, obstinate constipation, or inability to control the anal sphincter, should make one suspect tabes. Cardiac and laryngeal crises, while not properly belonging here, may receive passing mention, as in the great majority of cases they make their appearance when the disease is well established. Impotence in healthy middle-aged adults is also a very suspicious symptom and should receive due attention.

Cutaneous Symptoms.—Here may be briefly mentioned the various subjective sensory sensations which are the precursors of locomotor ataxia. These consist of various types of paresthesia, hyperesthesia, analgesia, and anesthesia. Cutaneous or deep-seated pains in any location, the origin of which baffles the diagnostician, may speedily be explained when the pupils and reflexes are tested.

Special Senses.—In a small percentage of cases the organs of special sense herald the approach of the tabetic process. Indistinctness or haziness of vision, in the absence of any other just cause, should lead to an examination which may show surprising conditions in the fundus. All primary optic atrophies, when unexplained by any other condition, point strongly to locomotor ataxia. Here may also be mentioned the various types of ptosis and ocular palsies, which supervene suddenly in the course of the disease.

Attacks of vertigo, dizziness, ringing in the ears, show auditory nerve involvement and mark the advent of the process in a small number of cases. Such symptoms should therefore receive due attention. A very small number of cases show in the incipient stage a blunting of taste and smell. Strong odors or spices are with difficulty recognized, and make little impression on the individual.

Just a word about the reflexes in the early stage of locomotor ataxia. I have found by observing a great number of cases that the condition of the knee jerk is of more value than that of all the other reflexes combined. I have repeatedly observed the presence of the elbow, wrist, cremasteric, and abdominal reflex in the absence of the knee reflex. It is well to remember that it is only very late in the disease that all reflexes disappear. The knee jerk is the earliest and most constant to disappear, and should be tested accordingly.

240 WEST ONE HUNDRED AND THIRTY-FOURTH STREET.

Maryland Buys a Sanatorium.—The "Mountainside Sanatorium," together with fifty-seven acres of land, at Mt. Alto Park, Md., has been purchased by the State and will form part of the State camp for the treatment of tuberculosis.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE

New York, August 31, 1907.

ANTHRAX.

Anthrax among human beings is everywhere a somewhat rare disease, and is especially infrequent in the United States. However, in South America the malady is fairly prevalent, and in that part of Great Britain in which are situated the woolen factories a considerable number of cases of anthrax occur. According to the annual report of the Chief Inspector of Factories and Workshops for Great Britain for the year 1905, fifty-nine cases of anthrax were recorded in Great Britain during that year, an increase of nine cases over the previous twelve months. Eighteen of these proved fatal, compared with ten fatal cases in 1904. The report also states that the incidence upon the Bradford district, the most important British wool center, has been proportionately heavy, a circumstance which has led to the appointment of a local commission with the object of investigating the matter and of devising more efficacious measures of precaution. In the same report attention is drawn to the recrudescence of the internal form of the disease, for whereas in the Bradford district during the five years 1899-1904 there were only six such cases reported, in 1905 out of a total of thirty-four cases, seven—all of which proved fatal—were of this form.

In fact, in all parts of England, in which industries connected with the manipulation of certain animal products are carried on, there has been a considerable increase in the occurrence of anthrax. Especially has this been the case with that form of anthrax known as "wool sorters' disease," or pulmonary anthrax.

Anthrax has been known from very early times. It is supposed to have been referred to in Exodus. Up to the end of the sixteenth century it was not suspected that the disease could be communicated from animals to men, and as recently as 1850 a thoroughly scientific observer, Hewsinger, who studied the disease, both in Russia and in Germany, came to the conclusion that the cause of anthrax was telluric. But in the same year Rayer and Davaine recorded that they had discovered in the blood of animals which had died from anthrax small rod-like bodies, which they presumed to be the cause of the disease. Later, Davaine announced positively that these minute bodies were the essential cause of the malady, and Koch in 1876 produced the disease in animals by inoculation. Pasteur confirmed all these results, and in 1877 demonstrated that the small rod-like bodies were indubitably the sole cause of the disease. So far as wool, in its relation to the incidence and spread of anthrax is concerned, it may be said that previous to the year 1837, when alpaca and mohair were first introduced into England, no specific disease had been associated with wool. With the importation of the alpaca and mohair wools, anthrax also made its appearance, and in 1847 suspicion arose that these new imports might be the cause of the affection. Investigations were carried on for many years, with the view of solving this mystery, and finally Dr. J. H. Bell of Bradford recognized that "wool-sorters' disease" was a form of anthrax.

The disease is contracted in its external or cutaneous form by means of abrasions of the skin. This type of the malady is oftentimes dangerous, but far less of a menace to the lives and health of wool-workers than is pulmonary anthrax, which is peculiar to wool-workers, is produced by inhalation of the disease germs, and is of an especially fatal character.

The distribution of anthrax is very widespread in animals; indeed it is geographically and zoologically one of the most widespread of all infectious complaints. It occurs with varying prevalence in most districts of Europe and Asia, of South Africa, and of South America. It occurs, but less frequently in North America, North Africa, Australia, and Great Britain. Up to the year 1877 wool-sorters' disease had not been known to attack other persons than the sorters of alpaca and mohair. After this date, camel's hair, Persian, and other dry, dusty, low-class wools were found to be infective.

At first sight the fact that the incidence of anthrax among persons employed in the wool industry of Great Britain is centered almost wholly in Bradford and vicinity and in Worcestershire would appear to be somewhat remarkable. The explanation is that it is only into these districts that the dangerous wools from Asia Minor and from Persia are brought. In the other parts of England and Scotland in which are woolen factories, colonial wool is chiefly dealt with. The outstanding feature of the situation is that the menace to the lives and health of wool workers in Great Britain comes almost entirely from imported wools, and of these, wools from British colonies are practically free from dangerous properties.

Anthrax in human beings is of interest to American medical readers only—fortunately—because it is a rare disease, the manifestations of which are both diverse and peculiar. In Great Britain, however, the interest in the malady is of a far more intimate nature, and efforts are being put forth to learn everything that can be learned concerning the disease, and to devise measures to stamp it out.

THE PRACTICAL SIGNIFICANCE OF THE WALCHER POSITION DURING LABOR.

As early as the sixteenth century, Mercurio empirically recommended a posture, similar to Walcher's, in all cases of difficult labor, without, however, understanding how it influenced the latter. Its use practically became extinct until, in 1889, Walcher emphasized the fact that certain changes in the position of a woman caused the length of her diagonal conjugate to vary a centimeter or so. Of late, Lange (*Der Frauenarzt*, May 17, 1907) has

again put the Walcher posture to test clinically and emphasized its usefulness. The patient is placed across the bed, with buttocks raised, but not brought beyond the edge of the bed; the legs are permitted to hang down, but must not touch the floor. As regards the mechanical effect of this position, he agrees with the explanation of Klein, who showed experimentally that when the sacrum is fixed, the ileosacral joint permits the pelvic ring to rotate on a transverse axis, situated behind the promontory. Thus, when the symphysis moves upward, the diagonal conjugate becomes smaller; when it moves downward the conjugate becomes larger. One can easily convince oneself of this change in length of the diagonal conjugate by making measurements with the patient in various positions. Lange found the greatest difference between strong flexion of the thighs and absolute hyperextension (Walcher), it amounting to 0.8 to 1. cm. The difference is only 0.5 to 0.7 cm. when the patient is measured in slight flexion and then in absolute hyperextension, and it is even less (0.3 to 0.4 cm.) when the patient is changed from the flat dorsal to the Walcher position.

The posture is indicated whenever there is a disproportion between head and pelvis, especially if it has to be overcome quickly, as in a breech extraction or extraction following version, when the head cannot be brought into the small pelvis through traction below or pressure above. From the time that this posture was adopted in all cases of contracted pelves in Leopold's clinic, the percentage of living children rose from 68.4 to 80. In cases in which the true conjugate was under 8 cm. it rose from 03.9 to 82.3. As the true conjugate is lengthened by this posture, the high forceps operation is much easier to do, and often is made unnecessary, as under anesthesia the head can be pressed into the small pelvis from above; in fact, Lange believes that forceps should not be used unless the latter procedure is possible. Several conditions must be fulfilled before we try to press the head down from above, the true conjugate must be above 7.5 cm., the membranes must be ruptured, and the cervix must be practically fully dilated. Lange also recommends the posture in cases in which the head is easily delivered, but when broad shoulders make trouble. As a temporary expedient it is of great aid in cases of contracted pelvis in which the head is slow in engaging, but it has the objection that the patients cannot remain in the position long, though they will generally do so for fifteen minutes at a time. As the anteroposterior diameter of the outlet is made smaller by this position, the latter must be discontinued, when the delivery is left to itself, as soon as the head has descended into the small pelvis.

Lately, Sellheim has added another indication. He claims that since the soft parts of the pelvic floor are attached to the sacrum and coccyx, and the Walcher position brings the lower end of the sacrum nearer to the symphysis, the soft parts become relaxed; he therefore uses it in forceps cases and in primiparæ when the perineum looks as if it were going to tear. It must, however, be remembered that this position makes the outlet smaller; hence it is important not to put the patient in it until the largest circumference of the child's head has passed the end of the sacrum, which has usually occurred when the posterior angle of the anterior fontanelle has passed the posterior fourchette. It is known to all obstetricians that the true conjugate is about 1 cm. longer in Walcher's position than in the lithotomy position, with thighs well flexed; yet in cases of contracted pelvis, when a version or breech extraction is done, we usually see the patient put on the operating table with her thighs well flexed. The Walcher posture, though well known to most obstetricians, is taken advantage of far too seldom, and it is allowable to believe that many more children would be saved if it were put into practice more often.

Eclampsia Without Convulsions.

By the term eclampsia we usually mean an acute morbid condition, which is characterized by a series of tonic and clonic contractions accompanied by complete loss of consciousness, and ending in coma or sleep. Pathologically, it is characterized by degenerative processes in the kidneys, liver, and heart, by areas of softening and hemorrhages in the brain, or by the formation of thrombi in these and other organs. This complex of changes, especially the formation of thrombi, is pathognomonic of eclampsia, and on the strength of this pathological picture alone, Schmorl, Bouffe de St. Blaise, Wendt, Meyer-Wirz, Esch, and Labhardt have made the diagnosis of this condition. The clinical course of their cases was very similar; the women all died in deep coma without convulsions. Two patients suffered with nephritis before pregnancy set in, another patient developed a slight albuminuria while she was in coma, while a large percentage of albumin was found in all the others. The pulse was always rapid, and vomiting was a constant symptom. In the case reported by Esch complete amblyopia set in before the coma, while the temperature rose above 103 F. Binder and Schlutius also reported cases which, by reason of their clinical course, were considered to be cases of eclampsia without convulsions. Both their patients complained of disturbances of vision during pregnancy, while soon after labor a rapid pulse and complete unconsciousness set in. The patients regained consciousness, but in the course of the next few days lapsed into unconsciousness several times; both finally recovered; their urine showed large quantities of albumin, which diminished as soon as the threatening symptoms disappeared. In the *Münchener medizinische Wochenschrift* of July 30, 1907, Dr. P. Reinecke again draws attention to eclampsia without convulsions, and relates the history of a young girl who felt perfectly well until she went into labor. She vomited a few times, complained of pain in the epigastrium, passed only very small quantities of urine, while her temperature rose to 103° and the pulse and respirations to 120 and 60 respectively; she died nine hours after the onset of the symptoms, going into coma three hours before death. At autopsy, degenerative changes were found in the heart, kidneys, and liver, but brain changes and thrombi were not found; nevertheless the clinical and pathological pictures together are characteristic of no other disease. Reinecke believes that a diagnosis of eclampsia without convulsions is justifiable in a patient displaying the above-mentioned symptoms and that the entire complex of pathological changes described by Schmorl and the others in their patients need not necessarily be present.

The Diagnostic Utility of Tuberculin.

There has been considerable discussion as to the utility of tuberculin in the diagnosis of doubtful cases of tuberculosis. On the one hand the agent has been condemned as dangerous, while on the other hand its intelligent and conservative employment has been accorded the highest commendation. It is at the present time realized that, when first put forth, tuberculin was administered in excessive doses for both diagnostic and therapeutic purposes, and sufficient discrimination was not exercised in the selection of cases. The limitations of the preparation and the indications for its use have gradually become more and more clearly defined with increasing experience, and the trend of opinion now seems favorable to its judicious and cautious employment. There are many cases in which a positive diagnosis is impossible on account of the absence of convincing and conclusive clinical and physical evidence, and it is just here that such an agent as tuberculin subserves a most useful and highly important purpose. Drs. John B. Hawes and Cleaveland Floyd (*Boston Medical and Surgical Journal*, May 30, 1907) have made a clinical study of cases of tuberculosis in the male and female departments of the Massachusetts General Hospital Out-patient Clinic, and on the basis of their experience they conclude that tuberculin is an agent of great value in the early diagnosis of tuberculosis. It is their opinion, however, that it should be used only as a last resort after all other means of making a diagnosis have been exhausted. Furthermore, it should be used only in carefully selected cases and by men properly trained and qualified to do this work. In initial doses of not more than 0.1 milligram they claim that it is not in any way dangerous. It was demonstrated that while it is perfectly practicable to use tuberculin to advantage, and to get good and trustworthy results in an out-patient department among ambulatory patients, it would be far better to have beds in the hospital for this purpose. It is much easier to obtain good results and to administer tuberculin properly if the patients are handled in groups or classes. If a patient has a history and presents signs that lead to a suspicion of tuberculosis, and in addition to this reacts to tuberculin, he should be treated as an early case of pulmonary tuberculosis, and furthermore the exact state of affairs should be explained to the patient or his friends.

School Hygiene.

One of the most instructive and interesting of the many medical, scientific, and social congresses which have been held recently in London was that on school hygiene. This subject has bulked very large of late years, and especially in this country. Indeed in some of our States we have shown the way to the rest of the civilized world in respect of school hygiene. Medical inspection of schools was inaugurated on a large scale in America. Great Britain has lagged somewhat strangely in taking the necessary measures to insure, so far as lies within human power, the health of her school children. True it is that she is now going forward in this direction at a rapid rate, but at least one of the measures which it is proposed to make law in certain parts of Great Britain, the feeding of indigent school children, is not likely to find favor with the authorities in this country. At the International Congress on School Hygiene which has just taken place in London, the many phases of school hygiene were discussed at length. Sir Lauder Brunton delivered the presidential address, and touched upon the need of plenty of fresh air and sunshine for growing town children. He also pointed out that the increased exercise due to the physicial training now carried on in all schools necessitated more food, and the question of how best to feed children at schools without interfering with parental responsibility was one which he trusted might be elucidated soon. One of the most important papers read was that by Sir Shirley Murphy, on the intimate relations between infectious diseases in the schools and among the population at large. School attendance concerned the general health, for it meant an increase of infectious disease. Thus the statistics of the ten years 1895-1904 showed that there were more cases of scarlet fever and diphtheria in London during the months when the schools were open. In regard to tuberculosis, the same speaker said: "If I may hazard a conjecture as to the trend of evidence concerning the conditions which cause this disease, I might say that infection by ingestion must increasingly be regarded as the largest factor in tuberculosis." He finally urged that the health of the population at all ages depended on the efficacy of school inspection, with which dictum few medical men will be found to disagree.

News of the Week.

The Sanitation of Cuba.—The occurrence of yellow fever at Cienfuegos has brought out the fact that since the former occupation of the island by U. S. troops, Cuba has lapsed into its old condition of insanitation. Governor Magoon has issued a decree nationalizing the sanitary systems of various cities of the island, and thus putting it in the power of the provisional government to take such measures as it sees fit to control the fever situation. This decree will coordinate all the health officers of the cities into one system, under the direct supervision of the medical authorities of the provisional government. The outbreak of the fever was due to the criminal carelessness of a physician who had a patient with yellow fever, and who neither reported the case to the authorities nor took any measures to screen the patient from mosquitos.

State vs. Federal Quarantine.—A despatch to the *New York Times* from Galveston states that the Federal Government will erect and equip a quarantine station there as soon as the board appointed by the Secretary of the Treasury has approved the plans and the site on Bird Island Reef, in Galveston harbor. Governor Campbell also announced that the State would continue in charge of the quarantine stations which it had offered to the Federal Government for $120,000, and a conflict of authority is probable. Officers of the U. S. Public Health and Marine Hospital Service recently pronounced the State's entire outfit worthless and the Texas quarantine ineffective.

Medical Inspection of Schools in Chicago.—The epidemic of scarlet fever, which prevailed in Chicago last winter, has taught the Health Department a profitable lesson. When the children begin their studies in the public schools early next month, 100 medical inspectors, graduate physicians under Civil Service rules, will begin a systematic campaign against measles, scarlet fever, and other diseases which have been accustomed to find their rallying points in the crowded schoolrooms. The city has been divided into one hundred districts, which in size and number of pupils to be looked after are

made as nearly uniform as possible. Each of the medical inspectors for the schools will be under the direction of one of the eleven regular medical inspectors of the Board of Health. Not only public schools, but parochial schools as well, will receive attention. As the total number of school children in the city approaches 400,000, each inspector will have approximately 4,000 pupils to look after. Medical inspection of this kind is not an absolutely new thing in Chicago, but this is the first time the work has been organized on such an extensive scale and also with such system and thoroughness.

Massachusetts State School for Crippled Children.—This school, which was established by the State Legislature in 1904, is for crippled children, who will be under treatment for their deformities at the same time that they are receiving a public school education. Later they will receive industrial training in some line of work for which they are fitted. The school buildings are now nearing completion in Canton. They are of brick and terra cotta, with dormitories and school buildings, hospital, heating plant, and laundry. Separate pavilions for the care of contagious diseases will be erected. Dr. John E. Fish has been appointed by the Governor as superintendent of the hospital school.

Cholera in the Far East.—It is reported that cholera has broken out among the Chinese in Shanghai and that several Europeans have also succumbed to the disease. Elaborate preventive measures have been adopted in the foreign quarter. Several other Chinese and Japanese coast towns are infected.

Cholera in Russia.—The sanitary authorities in Prussia are, it is reported from Berlin, watching with considerable concern the news indicating that cholera is spreading in Russia. The authorities have ordered a strict sanitary inspection of all vessels and rafts entering Prussian territory by the Vistula.

Diseases in Ridgway.—Dr. Arthur B. Moulton, Assistant Chief Medical Inspector of the Pennsylvania State Department of Health, reported to Health Commissioner Dixon that there were now ninety cases of typhoid fever, twelve cases of epidemic cerebrospinal meningitis, and sixteen cases of infantile paralysis in Ridgway. The local and State health authorities are cooperating. The source of the typhoid infection, a case of typhoid on the watershed, has been located, and everything possible is being done to prevent further spread of the disease.

Notifiable Diseases in Massachusetts.—Under a new law passed last year a uniform system of reporting diseases has been established by the State Board of Health. The old law stated that "smallpox, diphtheria, scarlet fever, or any other disease dangerous to the public health," must be reported, thus leaving the different city and town boards wide latitude; the new law, however, placing the whole determination of reportable diseases with the State Board of Health, renders the interpretation uniform. The State Board has prepared a list of eighteen notifiable diseases, tuberculosis and rabies having been added to the list of diseases previously used by most of the local health boards.

The West Virginia Anti-Tuberculosis League, with general offices in Charleston, is making progress all over the State, and local leagues are being formed rapidly. The objects of the League are: "To furnish information, instruct and teach ways and means of preventing tuberculous infection, and raising the standard of physical resistance. To arrest the progress of the disease and to effect cures in those who are now or may become infected with tuberculosis. To encourage the establishment of State, public, and private sanatoria in West Virginia. To centralize cooperative efforts by organizing local, county, and municipal leagues, to be under the immediate management of professional council, thus enabling victims of tuberculosis to obtain and have modern training and treatment within the confines of their respective homes."

Care of Convalescents from Insanity.—M. Ernest Daudet urges in the Paris *Figaro* a new philanthropic undertaking for the relief of those who are recovering from insanity, or who have been cured of it. According to statistics, in the Department of the Seine alone there is an annual discharge of patients from insane asylums of 2,400. Both M. Daudet and the Princess Lubomirska are taking an interest in these rather helpless people. As a rule, when they come back into the world, they are ill-fitted to make their way. They have lost confidence in themselves, are timid with others, and are likely to fall into intemperance and even crime. The plan proposed is to construct special workshops for this class of patients, where they can make a living while enjoying freedom. One such place was opened in Paris five years ago. The importance of caring for such unfortunates will be appreciated by anyone who has observed the effect of an asylum on the feelings and will of patients, however carefully they may have been treated.—*The Evening Post.*

Taxation of Medical Practitioners.—An earnest effort is being made by the Medical Society of Virginia to induce the next Legislature to abolish the State license tax. The *Virginia Medical Semi-Monthly* says that the committee of the State Society, under the chairmanship of Dr. J. B. De Shazo of Ridgeway, has done much good work in arousing the members to action. It says that of all the States of the Union only six require State license taxes on doctors. These States are Delaware, Virginia, North Carolina, Georgia, Florida, and Louisiana. Delaware assesses an annual license tax of $10. Virginia requires $10 of all who have practised five years or less; after that, $25 a year for those who reside in cities or towns, and $15 for country doctors. North Carolina charges a uniform license tax of $5, but no additional city or county tax is allowed. Georgia charges an annual license tax of $10, but no city or county license tax. Florida has an annual license tax of $10 to the State, and $5 to city or county of residence of the doctor, but it is expected that these taxes will all be removed. Louisiana charges license taxes on the basis of annual collections, the lowest being $5, for both State and parish, and intermediate sums up to $50, on $5,000 receipts. "But everybody seems to consider the demand so unjust that the law is not enforced except in a few instances."

Indigestibility of Chicago Potatoes.—The critical period in the condition of a lady from Detroit, Mich., who swallowed a small hat pin at the Auditorium Annex Hotel, Sunday night, while dressing for an automobile ride, has been passed, according to the attending physician. "We have located the pin," said the doctor, "and think an operation will not be necessary. The pin is near the appendix, and if it passes that point safely the patient will soon recover, otherwise an operation will be necessary. Mrs. Ferris is swallowing no liquid, and is sustained by potatoes alone. The potato forms a mass around the pin and is carrying it from her body. We have watched, with the *x*-ray, the potato food as it went through the various organs, tracing its progress inch by inch."—Chicago despatch to the *New York Times.*

Patent Medicine Vending in Connecticut.—At a meeting of county health officers of Connecticut at Eastern Point on August 15, the main subject of discussion was the best means to suppress the peripatetic venders of patent medicines, and it was decided that the most practical was the enforcement of a law prohibiting these men from selling their wares on their own recommendation without the advice or prescription of a registered physician. Even this law was ineffective in one instance related, in which a strolling company of nostrum venders in a city in the western part of the State had hired a registered physician to sit with them on the platform and to recommend the medicine to the purchasers. In this way they were saved from prosecution.

Memorial to a New Yorker in a French Hospital.—The family of the late Thomas E. Stillman of New York has presented to the city of Lisieux, France, an addition to the city hospital, where accident cases, especially automobile cases, are to be treated. The gift is made in memory of Mr. Stillman, who died in the hospital there a year ago from injuries sustained in an automobile accident. The foundation stone of the addition was laid on August 23. The Mayor of Lisieux, M. Cheron, made a speech of thanks to the donors. Their names will be inscribed upon the tablet reserved for those benefactors of the city.

James W. Sweet, one of the famous Connecticut family of "bone-setters," died on August 18 at his home in New Haven. His grandfather, father, and two uncles were all "natural bone-setters," and had a large clientele. James Sweet claimed to have "set" 35,000 bones during the thirty years of his career.

Prof. Marmorek, the inventor of the polyvalent antistreptococcus serum which bears his name, was one of the three leaders in the Zionist Congress held last week at The Hague. Another of the triumvirate was Dr. Max Nordau.

Dr. W. S. Bogart of Erie, Colo., has been appointed Professor of the Practice of Medicine in the Medical Department of Westminster University.

A Medical Library in Springfield, Ohio.—A new medical library has recently been started in Springfield, Ohio. The Board of Trustees of the Warder Public Library have very generously given a special room for the purpose, with excellent service by the librarian and assistants. Three physicians have been appointed as a medical library board to organize and maintain the same. These physicians are: *President,* Dr. C. H. Kay; *Vice-President,* Dr. Noah Myers; *Secretary,* Dr. T. M. Reade.

The John Crerar Library of Chicago announces that arrangements are in progress for the accommodation of its Department of Medical Sciences as part of its main collection at 87 Wabash avenue, N. W. Corner Washington Street, where it will be made available, at least in part, on and after August 10. The rooms now occupied in the Newberry Library building will be closed after August 3.

Five-Year Course at McGill.—According to the recently issued calendar of McGill University, Montreal, the course of study leading up to the degrees of M.D. and C.M. will, beginning with the present session, extend over five years instead of four.

The College of Medicine of the University of Wisconsin, which was authorized by the recent Legislature, will be opened and ready to matriculate students at the beginning of the college year in September, according to the preliminary announcement issued. The first two years' work of a medical college course will be given. Students thus may take all their preclinical work at the University of Wisconsin and then complete their medical studies with two years' clinical work at any medical college of recognized standing.

The Barnes Medical College of St. Louis has become the medical department of the University of Missouri, and with it the Centenary Hospital also becomes the property of the University. The first two years of the medical course will hereafter be passed at Columbia, the home of the University. The last two years of the course will be given in St. Louis.

Trinity Hospital in Varick Street was closed, it is said permanently, on August 16. The building used to be the rectory of St. John's Church, next door to it, but it first served as an infirmary some thirty-five years ago, and then was turned into a hospital, which was in charge of the Episcopal Sisterhood of St. Mary. The building was three stories in height and not adapted for hospital purposes. It is now in need of repair, and it is believed it will be torn down to make room for business buildings.

An Isolation Hospital in Grand Rapids.—The administration building of the contagious diseases hospital of the Board of Health of Grand Rapids, Mich., will, it is expected, be completed in September. There will be separate pavilions constructed for each of the usual infectious diseases.

The Third Council District of the Utah Medical Society, comprising the southern half of the State, was organized at Richfield on August 13. Dr. Frederick Clift of Provo was elected president, and Dr. C. W. Hasler of Lehi, secretary and treasurer.

The Sixth International Tuberculosis Conference will take place in Vienna on September 19, 20, and 21. The mode of infection of tuberculosis will be discussed at the opening session, and other topics for consideration will be the duty of notification and sanatorium expenses. Reports of progress in the crusade against tuberculosis in different countries will be received, and the international meeting at Washington in 1908 will be discussed in all its aspects, and honorary members will be nominated.

The XVI International Medical Congress.—It is announced that there will be a special section at this Congress, to be held at Budapest in 1909, devoted to neurology, and that this will be distinct from the section on psychiatry. The president of the neurological section will be Prof. Ernst Jendrassik, and the secretary, Prof. Charles Schaffer, Kálvin tér 4, Budapest.

The German Urological Society will hold its first meeting in Vienna, October 2-5, 1907. Discussions will be held on "Tumors of the Kidney," "Renal Calculus," and "Albuminuria." The secretary is Dr. Kapsamer, IX., Maria Theresienstrasse 3, Vienna.

Dannemora Overcrowded.—A mutiny recently broke out among the inmates of the Dannemora Hospital for Insane Criminals. In his report of the occurrence, the medical superintendent, Dr. C. H. North, implies that it happened because some of the worst of the inmates, who should have been in separate rooms, were, in consequence of the crowded condition of the institution, together in one of the dormitories and there laid their plans for the outbreak.

Obituary Notes.—Dr. Oliver Cromwell Comstock, formerly of Marshall, Mich., died in Brookline, Mass., on August 10, at the age of eighty-eight years. He was born in Fairfield, Saratoga

County, New York, his father being a well-known physician and a member of Congress. After studying medicine at the Fairfield Medical College and practising two years, he went to Philadelphia and continued his studies. At Trumansburg, N. Y., he practised his profession for several years, until his health gave way. He then went to Marshall, Mich., where he practised for a few years and then went into general business and farming.

Dr. William M. Cole of Sedalia, Mo., died of tuberculosis on August 9, at the age of thirty years. He was a graduate of the University Medical College of Kansas City in the class of 1903.

Dr. E. S. Ramsey of Kansas City died suddenly on August 13 of disease of the heart. He was born in Clinton County, Ill., in 1845, and began the practice of medicine in his native place in 1872. In 1889 he removed to Kansas City, where he practised up to the time of his death.

Dr. August Sander of Marble Hill, Mo., died August 12, at the age of seventy-three years. He was born in Germany, where he received his medical education and began the practice of his profession fifty years ago.

Dr. George Herbert Smith of Holyoke, Mass., died of Bright's disease on August 16, at the age of sixty-seven years. He was born in Chicopee Falls, and began the study of medicine in the office of Dr. Chaffee of Hartford, Conn., in 1861. He soon after entered the army and served for some time in the ambulance corps and in military hospitals. When he was mustered out he resumed the study of medicine and was graduated from Bellevue Hospital Medical School, New York, in 1865. He practised for a time in Illinois, but soon returned to the East and settled in Holyoke. He was elected mayor of the city in 1896, and served one term.

Dr. John Banta of Paterson, N. J., died on August 20 from pleurisy following the fracture of two ribs several weeks ago. He was a graduate of the Bellevue Hospital Medical School, New York, in the class of 1879. He was a member of the New Jersey State Medical Society and of the American Medical Association, and was physician to the General Hospital in Paterson.

Dr. John Hill, formerly a well known practitioner in Nashville, died of pneumonia at the home of his daughter near that city, on August 13. He had been in practice in and about Nashville for some forty years, and retired a few years ago.

Dr. Donald Macrae died at his home in Council Bluffs, Iowa, on August 14, of cardiac trouble. He was born in Scotland in 1839 and obtained the L.R. C. P., Edin., in 1861. He had practised in Council Bluffs for thirty years, during which time he had been prominent in public life as well as in the practice of medicine.

Dr. James M. Solomon of Boston and Attleboro died of disease of the heart on August 21. He was born in Attleboro in 1853 and was graduated from the College of Physicians and Surgeons in New York.

Dr. Theophilus O. Powell, superintendent of the State Sanatorium at Milledgeville, Ga., died August 18, at the age of seventy years. He was a graduate of the Georgia Medical College in 1859, and became attached to the State Sanatorium, then called the Georgia State Insane Asylum, as assistant physician, in 1862. He was widely known as an alienist.

Dr. D. E. Johnson of Mobile, Ala., died on August 15, at the age of sixty-five years. He was a graduate of the Medical College of Georgia in 1868.

Dr. J. M. Young of Alameda, Cal., died on August 14 from injuries received in a fall. He was born in Ireland in 1844, and was educated at Trinity College, Dublin. He studied law and practised for a time in Canada. Later he went to California and studied medicine there, obtaining his degree from the California Medical College in 1884. He had lived in Alameda twelve years.

Dr. Horace G. Leslie of Amesbury, Mass., died August 22, at the age of sixty-five years. He was born in Newbury, Vt., and went to Amesbury to reside in 1868, the year of his graduation from the Medical Department of the University of Vermont. He was active in public life, having been a member of the State Legislature and at the head of many associations for the improvement of the city in which he lived. He was a member of the Essex North Medical Society and of the Massachusetts State Medical Society.

Dr. Eliphalet Wright of Lee, Mass., died on August 22, at the age of ninety years. He was born in Hinsdale in 1817, and was graduated from the Berkshire Medical College, Pittsfield, in 1841. He practised first in Lee, then in Granville, and then again in Lee, where for over fifty years he had had an extensive practice. He was a practitioner of the old school, opposed to operations for appendicitis, and bleeding and sweating (and usually curing) his pneumonia patients. He was an active and prominent Mason.

Dr. Julia Meiklejohn of Clinton, Wis., died suddenly on August 16. She was a graduate of the Woman's Medical College of the Northwestern University, Chicago, in 1895.

Dr. Charles B. Tucker of Brooklyn died in the Hospital for Incurables, Fordham, August 26. He was born in Foxborough, Mass., sixty-seven years ago, and served as a surgeon in Grant's army in the Civil War. He had been suffering from paralysis because of a fall sustained a year ago. He obtained his degree from the Eclectic Medical School in 1865.

Dr. William E. Johnson, for many years a practising physician at Keyport, N. J., died recently at his home in Ontario, Canada. He left Keyport about two years ago.

Obituary.

SENECA D. POWELL, M.D., LL.D.,

NEW YORK.

Dr. Powell, who died at his summer home in Greenwich, Conn., on August 24, after an illness of three years, was born in Wilcox County, Ala., on January 5, 1848. When the Civil War began he was a cadet in the University of Alabama, which institution he left to serve as volunteer in the Confederate army. On the conclusion of the war he entered the Medical Department of the University of Virginia, from which he graduated in 1869; he then came to New York and obtained a second degree from the University Medical College in 1870. In 1871-2 he was an assistant inspector for the Board of Health in New York, and at the same time was chemical assistant to the chair of theory and practice of medicine in the Bellevue Hospital Medical College. From 1879 to 1882 he was adjunct professor in the chair of surgery at the New York University Medical College. In 1882 he became connected with the New York Post-Graduate Medical School as a lecturer on surgical dressings. Since 1887 he had been professor of clinical surgery in this institution. Dr. Powell was vice-president of the Medical Society of the County of New York in 1891 and president in 1893. He was president of the Medical Society of the State of New York in 1897-8.

Correspondence.

A CASE OF TRIPLETS.

To the Editor of the Medical Record:

Sir:—An extract in your issue of August 10 calls to mind a similar case in my early practice. While acting as house physician to the Sloane Maternity Hospital during October, 1888, I was appealed to by a woman to see her sister who lived in the neighborhood. She said several doctors had been called in, but after looking at the girl had declined to stay on. Hoping to get an unusual case for the hospital, I went with her and decidedly got myself into trouble. I found a young German husband who was in the last stages of phthisis sitting beside the bed of a seventeen year-old girl wife, who was having convulsions every few minutes and who was so waterlogged that one could hardly make out her features at all. She was so large with child that when I laid her on her back and removed my hands she would promptly roll back to one or the other side. Seeing I should need aid, and humanity forcing me to disregard a rule of the hospital not to do outside work, I sent for that good-hearted man and physician, Dr. Ogden Ludlow. While awaiting his arrival I put the girl deeply under chloroform and when he came I made an examination and found a head at the brim of the pelvis and the cervix wide open. Forceps was tried, but failing to lock I delivered the child by version. As it was badly asphyxiated I turned the woman over to Dr. Ludlow, while I tried to revive the infant. Suspecting multiple pregnancy, Dr. Ludlow then examined the woman and, finding a breech, brought the child out and began to work on it. My child now being dead, I again took charge of the woman, and to my horror found another head presenting. Another version brought this, the last, into the world. All the children were boys, and all weighed over four pounds. The aggregate weight being over fifteen pounds. There were three cords, two of which joined so that only two were implanted into the single placenta. None of the children could be revived, and after a sigh or two they all died. The woman had one slight convulsion after the anesthetic was stopped, but otherwise did well. Dr. Ludlow took charge of the case and afterward told me the woman weighed in normal condition only ninety-seven pounds.

L. E. Norfleet, M.D.

Tarboro, N. C.

OUR LONDON LETTER.

(From Our Special Correspondent.)

Hospital Funds—The Congress Season—Science at Leicester and Medical at Exeter—Discussions about Alcohol and Tobacco.

London, August 9, 1907.

Mr. Andrew Carnegie has given the King's Hospital Fund £100,000. This munificent gift is made unconditionally, but the donor expresses a desire for it to be used as seems best, adding the "more strenuously for reform the better." This is the fund founded by the King when Prince of Wales to commemorate Queen Victoria's Diamond Jubilee, 1897, and has therefore been in operation ten years. On his accession the King passed over the presidency to the present Prince of Wales. Many generous donors have helped to make it the great success it is with its invested fund of above a million sterling. Last year it distributed £111,000 among the hospitals. Its influence has been all along to promote wise economy and reforms in the direction of the reduction of expenditure. Perhaps it is to this policy Mr. Carnegie refers as reform. I hope expenditure in building will be discouraged. I have frequently referred to this subject and only last week mentioned that the Sunday Fund had moved in the direction of restraint by asking managers to consult the Council before embarking on enlargement. There are now about a thousand vacant beds in our hospitals, but a number of new schemes for adding to the accommodation for in-patients are before the public. Some of these are for enlargement of hospitals which cannot meet their present expenditure. Sir F. Currie, secretary of the Sunday Fund, lately spoke of this "building craze" in the instanced St. Mary's Hospital, where a great wing has been built, but the income is only sufficient to keep the old premises occupied. To fill the 1,000 vacant beds in London would cost about £100,000 a year, and it seems monstrous to add to them until they are provided for.

This is the season of congresses. Last week we had the British Association at Leicester and the Medical at Exeter. It is said there are some people who delight in these assemblies and do not like to miss anything of the kind. There are certainly some who would have liked to attend both meetings, and the secretaries are authorized to negotiate so that next year the two meetings shall not be held at the same time. This week we have two more congresses, which may help those who want a surfeit of such doings. They are the Housing and the School Hygiene, both of them international, and both in London. Before noticing these further it may be as well to say a word or two about the earlier ones. At Leicester the British Association meeting was, I am assured, as important and successful as its predecessors. I gave you a note last week on the president's address. This was followed by communications of absorbing interest. The constitution of the atom, the transmutations of radium and its allies, the fluid and solid theories of the ether, the nature of electrons, or, as Lord Kelvin calls them, electrions, these and other questions of high science were discussed by the recognized masters of their subjects, but I can only indicate them on this occasion on account of the mass of more strictly medical material. I must, however, mention an event which is as interesting as it is novel. The Mayor of Leicester, Sir Edward Wood, whose prodigal hospitality was remarked on all sides, gave a garden party which is perhaps unique on the picnic side of congresses. It was for the benefit of the most unfortunate of the citizens and made a party as pathetic as it was strange. The halt, the maimed, the blind were the guests at this garden party and were brought in ambulances, stretchers, and brakes from all parts of the city, while some made their way on crutches or were carried by friends. Blind people being led across the lawns, or sitting about and enjoying the fresh air, crippled children playing together, and other sick persons under tents made up a scene different from that of the park at other times, or a picnic at any time, and which those scientists who also went are not likely to forget.

Turning now to the Medical Congress, I may give you some notes that I have gathered, referring your readers to your special reports of the chief sections. The meeting is generally pronounced a success, as it was sure to be from the locality, Exeter being a favorite cathedral city and Devonshire claiming to be one of the most delightful counties of England. The popular lecture is rather a new departure, only two or three having been given. It was undertaken this year by Sir John Moore, who discoursed pleasantly on weather, climate, and health. He denounced the penuriousness of the Government in regard to meteorology, for the British Empire devoted a paltry £70,000 a year to this study, against some £290,000 granted by the United States Government. The relation between the birth-rate and death-rate was considered and the connection of infantile mortality with summer diarrhea. The seasonal mortality from various diseases was shown by curves, one of which indicated a falling fatality from tuberculosis in England and Scotland, with a tendency to increase in Ireland, but a relatively low rate prevailing throughout the western half of the island and higher rates in the urban districts of Dublin, Cork, Belfast and Derry. The fact was, he declared, that the slums and tenement districts of the old towns reeked with the poison of tuberculosis, and climate played a very subordinate part in the spread of the disease.

In the Section on Psychology a rather unexpected development took place. The set discussion was on alcoholism and insanity, and was opened by Dr. F. W. Mott, F.R.S., who gave some important statistics. He expressed the opinion that many effects depended on the quality of the alcohol as well as the quantity, and that the personal equation of patient and doctor must not be overlooked. He pointed out that there was a great difference between asylum and hospital cases. In the one there was a tendency towards brain disease. In the other, where this might be absent, the amount drank might be much larger before pathological changes occurred. Thus at Charing Cross Hospital 7.7 per cent. of the autopsies showed cirrhosis of the liver and 8 per cent of admissions were ascribed to alcohol. At Claybury Asylum only 1.8 per cent. had cirrhosis of the liver. His view seemed to be that the allegation that alcohol was the most important cause of insanity could not be maintained, and, apart from its abuse, the beneficial effects should not be denied or overlooked.

There were plenty of members to support this view and to go beyond it. In fact, I am informed, there was quite a lively defense of alcohol, and although Professor Halliburton thanked Dr. Mott for the moderation of his paper others took it as an encouragement to advance the old arguments in favor of moderate drinking.

One asserted that alcoholism was often the effect rather than the cause of insanity. Another thought it absurd to call it a poison. Another talked of the secondary effects—the narcotic—as beneficial, and so on until Dr. Yellowlees refused "to join in the glorification of alcohol" and was supported by several others. In the end the president of the section, Dr. T. C. Shaw, remarked that the question of alcohol would never be settled and there was much nonsense talked about it on both sides.

As a pendant to this discussion it is amusing to hear that at the Temperance Breakfast there was a large attendance, over which the Mayor presided, avowing himself a member of the Temperance League and telling his audience that in view of the number of victims the profession ought to give no uncertain sound. Dr. Davy was present and spoke of the increase of inebriety, especially among women, of the enormous expenditure on drink, and the large proportion in which it produced disease. Alcohol, he said, was not a necessity and very rarely useful in disease. Personally he was in favor of temperance and never would advise a patient to take it. Then, with strange want of logic, he said some teetotallers talked the greatest twaddle. Port wine had been referred to; he rather liked it and it was so great a poison that an uncle of his lived to be ninety-nine and used to consume a bottle a day. He thought a meal of cheese, bread, and light beer better than the tea, bread, and jam which so many children got. Of course, others followed with more scientific speeches and no one called Dr. Davy's twaddle, but as he was president of the Association and a guest of the League it hardly seemed the occasion for such remarks.

In another section, to relieve the deadly dullness which some complain of as prevailing in these meetings, there was a discussion on the allied subject of tobacco. In this, too, there was—may I quote?—"much nonsense on both sides," and some would say "twaddle." One seemed to think it the cause of innumerable diseases and of the deterioration of the race. Another spoke of the "invention of Satan," meaning, I suppose, the smoking of the plant, not tobacco itself. A "deadly poison" to one, a comfort to another, and so on.

I hardly think the Association shines in these conflicts, and some of our newspapers are talking about doctors disagreeing and saying when this is so each man will please himself.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 15, 1907.

A Soluble Bobbin for Intestinal Anastomosis.—John H. Cunningham tells of experiments which tend to show that in the maccaroni bobbin we have a device which, besides facilitating intestinal suturing and holding the sutured ends in position until firmly adherent, serves as a conduit for the intestinal contents and at a period of time not under twelve hours or later than thirty-six hours is digested and absorbed. Maccaroni recommends itself because it is easily digested in the intestines, is cheap, and can be made sterile in its preparation. The maccaroni used was a large size commercial maccaroni, cut into cylinders three inches long by three-quarters of an inch in diameter and bobbins of special design. These were sterilized by dry heat.

New York Medical Journal, August 17, 1907.

A Valuable Sign in Exophthalmic Goiter.—L. Napoleon Boston tells of this sign, which consists in: (*a*) Arrest of descent, (*b*) spasm, and (*c*) further closure of the superior eyelid. This phenomena is seen by all three of these features following one after the other in rather rapid succession as the eye is rotated from above downward. The spasm takes place after the patient has first rotated the eyeball upward, and then attempts to follow the finger of the operator as it is carried below a level with the chin. The superior lid follows downward with the pupil for a short distance, where it rests for an instant, then displays a slight spasm, with apparent slipping back, after which it continues to follow the pupil for an indefinite distance.

The Physical Reconstruction of School Children by Means of Fresh Air.—Linsly R. Williams calls attention to the fact that the New York Board of Health has records of examinations of nearly 200,000 children from five to fifteen years of age, which show the following defects: 60 per cent. undernourished, 66 per cent. need medical and surgical care, or better nourishment, 40 per cent. need dental care, 38 per cent. enlarged cervical glands, 31 per cent. defective vision, 18 per cent. enlarged tonsils, 10 per cent. postnasal growth. Facts in regard to school inspection are given to show the marked need of fresh air agencies, which exists in every large city. The entire value of the fresh-air home depends upon its character, and he explains this by giving a brief description of Sea Breeze at Coney Island. To obtain the best results for school children certain important principles must be maintained. To preserve the family as a unit, in order to teach the mother; to visit the family in its home; to ascertain its special needs, and to exclude contagion; to examine each child in order to advise properly the best thing for its health, for treatment, before, during, and after its stay; to follow up, after their return to their own homes, those children who may be sick or in need; and, finally, to maintain even at increased cost and apparently diminished usefulness the highest standard of efficiency.

Some Notes on Malarial Fever as Seen in the Jungle.—Charles S. Braddock says it is beyond dispute that the mosquito of a certain variety carries the germ of malaria and transmits it to individuals, but of still greater importance is the fact that persons can and do contract malarial fever when there are no mosquitos to give it to them. If an expedition is traveling in the jungle in either the wet or the dry season, the men traveling on foot first get malarial fever, the men on horseback rarely get it, while the men on elephant back will still more rarely and seldom get it. He attributes this seldom getting it by those high from the ground entirely to the miasma arising from the soil and rotting vegetation. In some bad districts one can smell the miasma. It is the immutable law of the jungle that if one sleeps on or near the ground, one must not change the clothing at once when wet by a tropical shower, get wet in the early morning from the heavy dew, and let the clothing dry, or the same after fording a tropical stream; or if one bathes in canal or river a short time after coming from a hard day's march, then fever will follow in a few hours afterwards. In the jungle one must boil the drinking water, and must clear away the jungle and let the sun in, and must not live close to or turn over the soil in the tropics; also, one must not neglect the mosquito curtain.

Eczema in the Second Year of Life.—Charles A. Kinch says that infancy comprises three years of life, and is divisible into two periods: Nursing, about twelve months; ambulant or runabout second and third years. In the nursing period by far the most common form of eczema is the neurotic. The typical picture of infantile eczema is vesicular, covering the face like a circular mask, avoiding the region of the eyes and nose. It is not parasitic. Scrofulous eczema is seldom seen in babyhood, seborrheic never. In the runabout period neurotic eczema is rare. Scrofulous eczema is common in the ambulant child. Seborrheic dermatitis in the runabout period takes on a character similar to the same disease in adults and responds with the same readiness to local treatment. It is in these cases that mild and brief applications of the *x*-ray, as in psoriasis, are helpful, and parasiticides accomplish brilliant results. Proper attention should be paid to tonic and corrective internal medication.

Journal of the American Medical Association, August 24, 1907.

The Diagnosis of Anemia.—R. C. Cabot summarizes the conclusions of his paper as follows: 1. In the diagnosis of anemia all facts must be considered. The etiological factors and the general physical diagnostic data are as important as the hematological findings. This is particularly true of the secondary anemias. 2. There are but two important types of anemia if we are to judge by the blood examination alone. To the first type belong the anemias due to hemorrhage, malaria, nephritis, and other diseases leading to increased destruction of red blood corpuscles. He also includes chlorosis in this class, so far as the blood picture is concerned, though elsewhere than in his conclusions he mentions the characteristic usual non-reduction of red corpuscles and low color index. Here he says it is distinguished wholly by the absence of etiological factors and the age and sex of the patient. 3. Pernicious anemia can usually, but not always, be distinguished by the blood picture alone. If this is supported by the history and physical examination the diagnosis is one of the clearest and surest in medicine. The most important single fact is the low red cell count with relative increase in hemoglobin. 4. The parasitic anemias are not always recognizable by the blood examination, but offer no difficulties in diagnosis if the eggs of the parasite are sought. Myelophthisic anemia is easily recognized by the evidences of its cause. The rare aplastic anemia has usually been observed in young girls and associated with severe purpura. The blood is like that in pernicious anemia, except that the erythrocytes are smaller and rarely contain nuclei.

The Treatment of Anemia.—S. J. Meltzer notices certain special methods by which he thinks there has been distinct progress in the treatment of anemia. The first of these is the method of direct transfusion introduced by Crile, whose experiments and results he considers a brilliant illustration of the value of vivisection to humanity. The second is the use of colonic irrigations in pernicious anemia, as recommended by Herter, and successfully employed by Ditmar and Hollis. Herter's discovery that special putrefactive processes in the intestines are due to the prevalence of anaërobic bacteria, particularly the *Bacillus capsulatus aërogenes*, and the parallelism of their presence with the symptoms of the disease suggested this treatment by injections, which Meltzer considers a valuable therapeutic advance. The third point touched on in his paper is the establishment of the clinical value of inorganic iron in the treatment of anemia. His explanation of the action of ingested iron is that it, like the carbohydrates, however it may be taken in, is converted into intermediate organic compounds and enters into the reserve iron stored up in the body, which is normally in excess of the needs of the system.

Fecal Bacteria.—The significance of the amount of bacteria in the feces is noted by J. Dutton Steele. Diet is an important factor governing their abundance, coarse and indigestible food favoring their increase, and it is probably from some such reason that the findings of Strasburger for Germany exceed those obtained in this country. The bacteria are increased with excessive bacterial activity in the stomach, as in achylia with diarrhea. They were also increased in some cases of hyperacidity, which is accounted for by assuming imperfect digestion or chemical irritation from excess of hydrochloric acid, the normal intestine being assumed to have a certain power of protection against bacteria. Poor starch digestion gave in one case twenty-seven per cent., and when the starch in the diet was reduced one-half, the bacteria fell to fourteen per cent. The reaction of the stool in this case was strongly acid. The bacteria were increased in one case of chronic cholecystitis and in one of pancreatic gumma. The growth of the intestinal bacteria is also increased by the administration of various so-called intestinal antiseptics. The intestinal bacteria are decreased in amount with diets giving a small residue, in uncomplicated atonic constipation, and apparently also in jaundice. Steele does not consider this last due to antiseptic action of the bile, but rather to the reduced diet. Certain intestinal antiseptics (bismuth salicylate and beta-naphthol) reduce the quantity of fecal bacteria in normal persons, but it does not necessarily follow that this would be the case in abnormal conditions. Steele thinks that the opposite would be more probable.

The Physiological Effects of Gastrojejunostomy.—H. J. Paterson defends the operation of gastrojejunostomy from certain charges that have been made against it, summing up his conclusions as to its effects on the physiology of digestion substantially as follows: 1. A certain amount of bile and pancreatic juice enters the stomach after gastrojejunostomy, but the amount is small and has no bad effect. 2. The acidity of the gastric contents is markedly reduced, usually about thirty or thirty-five per cent. This is due partly to a reduction in the total amount of chlorides secreted, partly to the partial or complete neutralization of the free HCl by the alkaline bile and pancreatic juice, and probably also to earlier stimulation of the pancreatic secretion with compensatory earlier fall of the gastric secretion. In gastric ulcer cases the removal of spasmodic stenosis of the pylorus likewise tends to diminish the total acidity. 3. Gastric digestion is only impaired, not lost, after gastrojejunostomy. 4. The gastric motility if previously normal is practically unaffected. Gastrojejunostomy is therefore not a drainage operation. Its good effects in gastric ulcer are due to the reduction of the acidity of the gastric contents. 5. Gastrojejunostomy has no material effect on the metabolism of the human body, the percentage of nitrogen and fat absorbed being within the limits observed in healthy persons. This chemical fact is confirmed by the result of clinical observation.

Factors in the Production of Coagulation Necrosis.—D. H. Bergey states that coagulation necrosis is usually defined as that form of death of tissue in which the proteid suffers changes similar to or identical with coagulation. He discusses the influence of bacteria in producing coagulation necrosis and the other alterations of the colloids in the body, and treats briefly the lines of experimentation pursued. The results which he has made indicate: (1) The coagulation of blood serum through bacterial agency is induced directly and indirectly by a coagulating and a carbohydrate-fermenting enzyme produced by the bacteria; (2) that the inhibition of the effects of the carbohydrate-fermenting enzyme alone, through neutralization of the organic acids produced will annul or materially reduce the pathogenic effects that would otherwise ensue; (3) if some safe and certain method can be devised for overcoming this mode of offense by the bacteria we shall possess an additional defensive measure against bacterial action in the body.

Sewage Purification.—G. T. Moore concludes that the septic tank, under ordinary conditions when there are no trade wastes calculated to retard bacterial action, is well suited to remove a considerable percentage of the suspended matter in sewage. It requires but a moderate space, can be cheaply run, but cannot be considered a complete method of sewage disposal and needs to be followed by some process that will expose the effluent to further purifying action, to give a satisfactory result. The chemical method, he thinks, gives promise for the future, but how far its applicability extends remains to be seen. If a sterile as well as an oxidized effluent is demanded, it is not unlikely, he thinks, that the result can be obtained by combining a germicide with chemical precipitation methods as cheaply and satisfactorily as by other means that would have to be employed. The local condition must largely govern the choice of method of sewage disposal, and no plan ought to be adopted until after careful and thorough investigation of all the conditions by competent experts. Many failures have been due to the lack of this, as well as to gross mismanagement or neglect.

The Lancet, August 10, 1907.

Bodily Posture and Cardiac Physical Signs.—William Gordon sums up briefly by stating that in most cases the change from the erect to the recumbent position: 1. Raises and narrows the normal cardiac dullness. 2. Makes the first heart sound duller and the second sharper, thus producing the classical "lub-dup." 3. Diminishes the antero-posterior diameter of the chest. 4. Markedly narrows the dullness of an enlarged heart. 5. Increases the loudness and area of audibility of (*a*) "hemic murmurs" both at the base and apex; (*b*) mitral and tricuspid regurgitant murmurs; and (*c*) aortic stenotic murmurs. (Some of these murmurs may be audible only in the recumbent posture.) 6. Lessens the loudness and area of audibility of (*a*) the "venous hum" in the neck; and (*b*) the presystolic murmur of mitral stenosis. (Some of these murmurs may be audible only in the erect posture.) 7. Leaves unaffected the murmur of aortic regurgitation. 8. Increases the loudness of the accentuated pulmonary second sound. 9. Makes more marked the reduplication of the reduplicated second sound. (In some cases the reduplication is heard only in the recumbent position.) 10. Causes the partial or complete disappearance of the cardiac dullness in certain cases of cancer in their later stages.

Further Researches into the Etiology of Cancer: Note Upon Certain Histological Features of Carcinomatous Tumors Revealed by an Improved Ammonio-Silver Process.—W. Ford Robertson and M. C. W. Young have made recent histological observations which are essentially a continuation of those already recorded in the *Lancet*. Distinct advances as regards the clearness of the histological pictures have been obtained by stronger silver impregnation and by the employment of various agents which practically remove either the silver deposit or the gold which has replaced it. For the removal of the silver deposit platinum bichloride has been of most service; for the removal of the gold deposit potassium cyanide has been used. A still further and very striking improvement has recently been effected by fixing the tissues with corrosive sublimate. The necessary directions for carrying out this improved ammonio-silver process are given. The general result of these new investigations has been to obtain a considerable amount of additional evidence of the occurrence of special intranuclear bodies of the nature of those previously described, to show that structures morphologically identical with the *Spirochæta microgyrata* can be demonstrated in human carcinomata, and to confirm the previous observation of the occurrence of small nucleated bodies, evidently of amœboid character, in such tumors. They also record some observations upon the Jensen mouse tumor, including that of the presence of a body morphologically identical with the spirochete described by Gaylor and Calkins.

A Method of Amputation at the Ankle-Joint Which Leaves the Heel Intact.—C. Gordon Watson describes an operation which resembles in many respects Le Fort's modification of Pirogoff's operation and may be termed "transcalaneal amputation of the foot." He concludes that: (1) it will be found that with the incision given the margin of the plantar incision will be about from one to two inches longer than the margin of the dorsal, so that in suturing slight puckering of the plantar flap will be necessary. Any attempt at lengthening the anterior flap at the expense of the plantar offers two disadvantages—dan-

ger of sloughing in the dorsal flap, which consists only of skin and is not too well supplied with blood, especially in paralytic limbs, and also a risk of getting the ultimate scar too near the sole. (2) At the completion of the operation the plane of the sole remaining will not be horizontal, but tilted forwards and upwards at an angle which corresponds to the position of the os calcis and sole in the normal foot. (3) The tendo Achillis having been divided there is no likelihood of the os calcis becoming displaced backward, and lateral displacement is prevented by retaining the malleoli. It is important to remove all cartilage and to get accurate adaptation of the bony surfaces before fixing. (4) The results of the two cases reported offer encouragement to repeat the operation in similar cases. The resulting stump is certainly as good as, if not better than, that produced by any other known amputation at the ankle. The operation should be applicable also to some cases of disease and injury in which it is possible to leave the os calcis.

A Case of Streptococcic Septicemia.—W. Greenwood Sutcliffe and H. Wansey Bayly report the treatment of a case of streptococcic septicemia by Wright's method with a vaccine made of organisms obtained from the patient's blood, the inoculations being controlled by the opsonic index. The patient recovered. The chief features of interest in this case is the development of the second threatened focus in the left thigh which might be fairly ascribed to the vaccine and the administration of citric acid. There was a marked general improvement after each inoculation with the vaccine, which in almost every case was followed by a rise in the index within twenty-four hours, associated with a fall in the temperature. The boy was throughout kept out of doors from morning till night. The infection evidently took place at the time of operation, the streptococci no doubt being already present in the discharging sinus and gaining admission through the wound in the vein into the general circulation and setting up rigors and a general septicemia fifteen days later.

British Medical Journal, August 10, 1907.

Occurrence of Epileptoid Attacks in Tachycardia and Bradycardia.—Fred. Hugh Clarke considers the clinical aspects of these two conditions and suggests that tachycardia is a pure neurosis, characterized by a great increase in auricular contractions from disturbed nervous influences. After a time, from overexertion, fatigue in the conductivity of the band of His occurs; missed impulses result, causing longer or shorter delays in the ventricular contraction. When these delays are sufficiently prolonged, cerebral anemia is produced, followed in due course by certain nervous symptoms. Tachycardia, being a neurosis, is commonly recovered from. In bradycardia the ventricular pauses are due to structural changes in the band of His, and, therefore, the condition is never recovered from. Life, according to Balfour, is rarely prolonged for more than three or four years. Rest, both physical and mental, is of the greatest importance in the treatment, with head low and foot of bed raised. Any deviations from health should be attended to. In tachycardia nerve tonics seemed to do good. In bradycardia strychnine hypodermically, with heart tonics, seemed to have been of use. Osler records a case of recovery after treatment with iodide of potassium.

The Prevention of Valvular Disease.—Richard Caton says that in acute rheumatism and most of the pathological states in which valvulitis occurs we can secure a large measure of rest and of the conditions favorable to heart repair if we take sufficient trouble. We lessen pain and fever by appropriate measures; we insist upon the most absolute quiet and rest, alike of body and mind; a light diet is given and, if necessary, some sedative. Sodium or potassium iodide is given. Small blisters are applied over the distribution of the first four dorsal nerves between the clavicle and the nipple. The effect of the first group of measures is to slow the heart and diminish its amount of work, offering it the opportunity of self-cure. The second measure stimulates the curative activity of the part. Of these two measures of treatment, the prolonged period of rest is by far the most important. The rest should continue for six or eight weeks or more. By degrees the bruit lessens, becomes intermittent, and at length vanishes. He has witnessed the workingman whose incipient heart lesion has been treated, thus fulfilling year after year his full measure of hard work without dyspnea and without discomfort. The rest treatment must be commenced fairly early before too great an amount of structural change has taken place.

Malnutrition in an Infant Due to Excessive Putrescence in the Alimentary Canal Successfully Treated by Lactic Acid Bacilli.—A. Veitch says that in 1904 Metchnikoff made a strong plea for the systematic introduction of the lactic acid bacilli within the alimentary canal, both as a preserver of health and as a remedial agent in disease. The recent laboratory work and clinical experiences give strong support to the views of Metchnikoff and suggest that in soured milk we have a valuable intestinal antiseptic. He reports a case which seems to warrant the adoption of sterilized or pasteurized milk treated by pure culture of the lactic acid bacillus in all cases of malnutrition in children where intestinal decomposition is found to be excessive.

Berliner klinische Wochenschrift, August 5, 1907.

The Bier Treatment in Gynecology and Obstetrics.—E. Runge finds that in gynecology this form of treatment is best suited for inflammatory conditions of the cervix and for those of the endometrium of the uterine body, i.e. in all forms of endometritis. To treat cervix conditions he inserts a glass speculum into the vagina, the one end fitting snugly over the cervix, the other being attached to a suction apparatus. While this method is also used by many in endometritis, he claims it is practically useless, as the suction causes the two walls of the uterus to come in close contact with each other, so that there is no uterine cavity which can communicate with the suction apparatus. In order to treat these cases properly he first inserts a dilator into the uterus; this consists of a glass rod surrounded by a wire netting which fits closely to the rod while the latter is being inserted. After the dilator is in the uterus a screw at the end of the rod is turned, which in turn raises the wire netting from the rod and thus keeps the uterine walls separated and the cavity in communication with the suction apparatus. His results in these conditions with the Bier treatment were good, but no better than those obtained with other methods, while it took longer to attain the same results. He warns against keeping the suction up too long and against pulling on the apparatus when it is in place, as shock and uterine displacements have been caused by not heeding these warnings. The suction is usually kept up five minutes, at five-minute intervals, one sitting lasting from one-half to three-quarters of an hour and is repeated every two or three days. He has not had enough experience with metritis, parametritis, and amenorrhea cases to report on the value of this treatment in these conditions. In obstetrics he has tried it in septic endometritis and subinvolution cases with some good results. In mastitis it prevents suppuration when applied early, its main use, however, he finds in cases of suppurative mastitis, where the suction apparatus is applied for ten minutes at a time, at ten-minute intervals, for three-quarters of an hour twice a day, but only after one or two small incisions have been made. It certainly has the advantage over the more radical surgical procedures in that it does not leave large scars, destroys less breast tissue, cures more rapidly, and thus permits the child to be put back to the breast sooner, while it keeps up the secretion of milk by its suction even though the child does not nurse.

Münchener medizinische Wochenschrift, July 30, 1907.

Vicarious Respiration.—Geigel prefers this name to compensatory or vicarious emphysema, which is usually applied to a lung which is doing part of the other's work in addition to its own. When a healthy lung does such additional work the extent of the respiratory excursion is increased, quite a different condition than the one which exists in emphysema. Of course, when such a lung is overworked a secondary emphysema may set in, when its respirations must cease to be compensatory; for these reasons he uses the name vicarious respiration. As regards the mechanism of the latter he believes that the inspiratory muscles play the greatest part. In some cases only the muscles of the healthy side are brought into play, for instance, in large pleural effusions with total compression of the lung. In other cases where the slightest excursion of the thoracic wall is still possible both sides are used. He recites a case proving this. An aneurysm in the mediastinum caused a bronchial stenosis on the left side, so that respiratory sounds were practically not heard over the left lung. On being skiagraphed the tumor was seen to move one to one and a half centimeters to the left with each inspiration, the respiratory muscles of both sides having been used. The case, furthermore, showed that a healthy lung does not only expand upward, downward, and outward, but also towards the affected lung, a phenomenon of vicarious respiration not described heretofore. The movements of the mediastinum he claims are brought about by the inspiratory muscles of the diseased side. He thinks that possibly these movements of the mediastinum may be of value in diagnosing between bronchial stenosis caused by an aneurysm and bronchial stenosis caused by an infiltrating tumor.

Hot Air Treatment of Chilblains.—Hornung refers

to the recent articles of Ritter and Mirt in which they recommend this treatment for chilblains. He reminds us that this is an old household remedy which was in vogue in the first half of the last century, though its mode of application was a little different. The parts affected were rubbed with petroleum and then held as long as possible near an open fire, sometimes for a whole afternoon. After several days the chilblains disappeared. Horning admits that the petroleum played no part in the cure.

Deutsche medizinische Wochenschrift, August 1, 1907.

Primary Arteriosclerosis of the Pulmonary Artery.—Monckeberg distinguishes between an arteriosclerosis of the pulmonary artery, which is secondary to an increased blood pressure caused by a mitral stenosis or some lung disease, and a primary one not dependent on any heart or lung trouble. The former is an interesting condition found at autopsy, but one which had no influence on the clinical picture of the case; the genuine primary arteriosclerosis, on the other hand, is the cause of clinical symptoms and pathological changes in the heart. It is a rare condition of which he could find only two complete accounts in literature. After giving a synopsis of these cases he relates the history of two cases of his own with detailed microscopical and macroscopical post-mortem findings. In none of the cases was the correct diagnosis made during life. Twice a congenital heart lesion was suspected; in one of his cases Basedow's disease was diagnosed, in the other a mitral insufficiency with lost compensation. Clinically the lungs were usually found normal, the right heart was hypertrophied, various murmurs were heard over the cardiac area, the pulse was rapid, but regular, the patient was cyanosed, and towards the end the signs of a tricuspid insufficiency set in. At autopsy the lungs were found normal, the right heart enlarged, and its walls hypertrophied, the pulmonary artery and its main branches dilated, while the lumen of the smaller branches was found diminished throughout both lungs. The microscopical and macroscopical changes in the pulmonary artery and its branches resembled those found in secondary arteriosclerosis of the pulmonary artery and in arteriosclerosis of other arteries. No organic valvular disease was found nor any lung conditions which might have caused the hypertrophy of the right heart. The autopsy findings left no doubt that the greatly diminished lumen of the smaller branches of the pulmonary artery were the cause of the right-sided cardiac hypertrophy and the relative tricuspid insufficiency with its symptoms. As there was no cause for any increased blood pressure in these cases, this could not have been the cause of the arteriosclerosis. The only explanation he can offer for the condition found is that since the patients were all young, the walls of the pulmonary artery and its branches may have been congenitally weak, so that finally even the normal blood pressure became too much for them and caused the arteriosclerosis.

Bier's Hyperemia in Otology.—Leutert reviews most of the articles published by others on the value of the Bier treatment in otology. He does not share the opinion of those who claim it has already been proven useless in this branch of medicine, but is inclined to believe that it deserves further trial in a certain class of cases in which good results have been obtained. He furthermore holds that this form of treatment should be confined to ear clinics where the patient can be constantly watched and immediately operated upon if necessary. The deductions which he draws are as follows: (1) In chronic middle ear disease the treatment is useless. (2) In mild, fresh cases of otitis media paracentesis relieves the patient much quicker than the hyperemia artificially produced. (3) Fresh, severe cases of otitis media, with or without mastoid tenderness, in which an early paracentesis was necessary and in which the Bier treatment was instituted at the same time, are not cases by which we should judge the efficiency of the latter form of treatment, since the good results were probably due to the paracentesis. Many of the reported cases of cure with the Bier treatment are of this kind. (4) In mastoid disease the treatment is dangerous on account of the close proximity of the sigmoid sinus. Bier claims that artificial passive hyperemia increases the area of inflammation, which increase amounts to possibly one centimeter in an extremity and is of no account; but in the ear one centimeter is a big distance and may bring one very close to the sigmoid sinus which may then become diseased. The danger of such a complication is greater when there is no external opening in the mastoid process and supervening abscess through which pus can drain. Four cases of mastoiditis in which there was no such opening and in which the hyperemia treatment was tried ended with sinus involvement. While the Bier treatment may not have been the sole cause of the latter complication, it probably aided in bringing it about. (5) In a certain class of cases with a superficial skin abscess in the mastoid region the treatment might be of value. Bier's and Heine's successfully treated cases came under this head. They always first incised the skin abscess without knowing, however, whether the bone was intact or not. Probably the mastoid abscess had ruptured into the subcutaneous tissue, in which case their good result can easily be explained by the free drainage which their skin incision with suction brought about. As Bier and Heine were not certain whether in their cases the bone was intact or not, it remains to be seen whether their method of treatment will be efficient in cases of mastoiditis with a superficial skin abscess where the bone has remained intact. (6) The treatment is contraindicated in all cases of mastoid disease in which complications are suspected.

French and Italian Journals.

Alcohol and the Infant.—Raoul Brunon draws a painful picture of the increase of drunkenness in France since spirits have been substituted for the wines of the country as a common drink. It has become the custom to give brandy and spirits to infants at the breast to make them sleep, and to children at their meals. The nurse takes spirits to increase her milk, and the pregnant mother to help the development of her child. The workman drinks brandy three times daily. The infant is poisoned before birth, cursed with the paternal heredity, and made a toper in childhood. Many children suffer as a result from skin and intestinal diseases, and the number of deaths is appalling. Nervousness, insomnia, bad temper, and constant crying are the results in young children. Older ones are the victims of tuberculosis, epilepsy, and crime. Absinthe is the drink of the young man, and it is the cause of the majority of crimes among the young. The effect of this state of things is evident in the small number of children and the large increase in crime, as well as in the smallness of the race, evidenced by the necessity of reducing the required stature in the French army.—*Le Bulletin Médical,* May 15, 1907.

Relations Between Acromegaly and the Sexual Function in Women.—Serafino Patellani has made experiments, as well as examined the histories of 145 collected cases. As a result of his studies he gives us some definite conclusions. He believes that the absence of menstruation bears a definite relation to the presence of the disease. Experimental studies of the hypophysis have convinced him that its function is to regulate metabolism, and that its destruction causes accumulation of toxic substances and poisoning of the system. He finds that the classic form occurs most frequently between the ages of twenty-one and twenty-five years, and in virgins or sterile married women. It may result from injury, infective diseases, prolonged lactation, and uterine atrophy. It never occurs before puberty or after the menopause, but is a disease of the sexual period. The normal menopause may be considered a physiological acromegaly. Amenorrhea is not only a symptom, but bears a causal relation to the disease. Lactation may end in uterine atrophy, followed by amenorrhea. In all cases of acromegaly in which the genitals were examined during life or after death these organs were found small or atrophied. Ovulation may go on during the disease, and pregnancy occur, but lactation will generally precipitate the development of the disease. It may exist unobserved for from one to five years.—*Annali di Ostetricia e Ginecologia,* March and April, 1907.

Experimental Researches on the Specific Value of Certain Sera in Infections by Streptococci and Pneumococci.—Raffaele Chirolanza says that the streptococcus and the pneumococcus are germs that frequently produce peritonitis. In young children these infections are not very serious, but in adults death is generally the result. The author has made experiments to ascertain whether by the use of sera effects cannot be obtained that may aid in the cure and prevention of these infections. Possibly a preventive action may be obtained in infections consecutive to laparotomy. There are several varieties of streptococci found in different diseases, whose virulence and effects are different. The author has made use of the sera of Aronson and Tavel, injecting them into the abdominal cavity of rabbits. He made use of a streptococcus from a human subject in producing the infection to be combated. The serum used had no beneficial effects in the case of streptococcus infection in rabbits. The serum does not act uniformly because there are several varieties of streptococci. The ethereal serum of Pane in small doses has a slight effect in the case of nonvirulent streptococci, but when the germs are virulent the serum has no preventive action. Against the pneumococcus the serum of Pane has a marked and constant preventive action.—*Il Policlinico,* June, 1907.

Book Reviews.

A Manual of the Diagnosis and Treatment of the Eye. By Edward Jackson, M.D., Professor of Ophthalmology in the University of Colorado. Second Revised Edition. Philadelphia and London: W. B. Saunders Company, 1907.

The second edition of Jackson's work forms a volume of 615 pages. It is well printed and sufficiently well illustrated by original cuts. The work is intended for the use of the student and general practitioner and is admirably adapted for the purpose. The revision of the first edition has been thoroughly done. There have been many additions, particularly to the part devoted to diseases of the eye. The descriptions are condensed, but are clear and quite comprehensive. The volume is one to which the phrase "multum in parvo" may be very appropriately applied. The work is particularly strong in the department of practical optics; nevertheless, it is well to the front in all of its various parts. An excellent feature is the bibliography, which gives reference to many of the recent exhaustive articles on all of the topics discussed, enabling the student to continue further the study of any subject in ophthalmology.

Manual of Anatomy, Systematic and Practical, Including Embryology. By A. M. Buchanan, M.A., M.D., C.M., F.F.P.S. Glas., Professor of Anatomy in Anderson's College, Glasgow; Examiner in Anatomy for the Triple Qualifications of the Scottish Licensing Bodies; Examiner in Anatomy and in Physiology for the Double Diploma, and Examiner in Anatomy (Human and Comparative) for the Fellowship of the Faculty of Physicians and Surgeons of Glasgow; Ex-Examiner in Anatomy to the University of Glasgow; Formerly Senior Demonstrator of Anatomy in the University of Glasgow. Vol. II. Chicago: W. T. Keener & Co., 1907.

The second and concluding volume of this excellent work on anatomy treats of the abdomen and its contents, the thorax and its contents, the head and neck, the nervous system, and the organs of special sense. An appendix contains the Basle Anatomical Nomenclature and a glossary of anatomical terms, giving sometimes the definition, sometimes the derivation, of some eight or nine hundred words. This work is one which ought to meet well the needs of the student during dissection, for the descriptive portion is well arranged, with heads marked in distinctive type, and not too voluminous. The pictures, of which there are 629 in the two volumes, are plain, but clear, and a number are colored to distinguish the arteries and veins. The book is of convenient size for the dissecting room, and the binding is such that the volume will lie flat when opened at any page. The work is hardly elaborate enough to compete with any of the large treatises on anatomy now in use, but as a dissecting manual it can be heartily commended.

The Common Bacterial Infections of the Digestive Tract and the Intoxications Arising from Them. By C. A. Herter, M.D., Professor of Pharmacology and Therapeutics in Columbia University, Consulting Physician to the City Hospital, New York. New York: The Macmillan Company, 1907.

Now that it has been clearly shown how large is the part played by the intestinal flora in many apparently remote morbid processes the appearance of the present volume is to be regarded as a boon to the profession. It is especially valuable, however, not alone from the fact that it offers a summary of what has been learned from and is suggested by the work of others in this field, but in that it comprises the results of the enormous amount of original work relating to the subject carried out in the author's laboratory, and contains a wealth of new information that seems destined to form what may almost be termed a new point of departure in diagnosis and treatment. The first chapters are devoted to a discussion of the bacterial flora of the human digestive organs in health, and the bacterial processes in the gastrointestinal system of normal and bottle-fed nurslings, children, adolescents, and adults. The intestinal bacteria of carnivorous and herbivorous animals are taken up and the methods used in investigating and classifying the gastroenteric bacteria are described. The following chapters treat of the common bacterial infections of the digestive tract, first from the standpoint of the organism concerned and then in regard to the products of the fermentative and putrefactive processes. The types of the chronic excessive intestinal putrefactions are grouped under the indolic type, the saccharo-butyric type, and the type consisting of a combination of these two. Finally the subjects of prophylaxis and treatment are taken up, and the book closes with a chapter in which the acute and chronic enterogenic infections are considered from the sociological standpoint. The prevention of the acute forms, such as dysentery, typhoid fever, and the milk-borne infections of infants, has long occupied the attention of hygienists, though their efforts are even now inadequate to the importance of the issues at stake, but the injurious effects of the more insidious chronic enterogenic diseases are none the less real because their nature is only rarely recognized, and the economic loss to the community that they entail is almost beyond calculation. Dr. Herter's book should serve to point out the gravity of these intoxications and to direct the attention of the profession to the means for their control. The problems involved are many and difficult, but much has already been gained in regard to the means available in combating them. This volume will no doubt prove an incentive to much further investigation.

Tics and Their Treatment. By Henry Meigs and E. Feindel. With a Preface by Professor Brissaud. Translated and Edited with a Critical Appendix by S. A. K. Wilson, M.A., M.B., B.Sc., Resident Medical Officer, National Hospital for the Paralyzed and Epileptic, Queen Square, London. New York: William Wood and Company, 1907.

In this volume will be found an exhaustive, yet readable, account of tics. It is unfortunate that the term tic should be so frequently misapplied and misunderstood, and the authors of this work are at considerable pains to clear away much of the misconception that has surrounded the word. Their definition of tic, though lengthy, is worth quoting: "A tic is a coordinated purposive act, provoked in the first instance by some external cause or by an idea; repetition leads to its becoming habitual, and finally to its involuntary reproduction without cause and for no purpose, at the same time as its form, intensity, and frequency are exaggerated; it thus assumes the characters of a convulsive movement, inopportune and excessive; its execution is often preceded by an irresistible impulse; its suppression is associated with malaise. The effect of distraction or volitional effort is to diminish its activity; in sleep it disappears. It occurs in predisposed individuals, who usually show other indications of mental instability." The book begins with a chapter on the confessions of a victim to tic; this is followed by chapters on the history of the term, the pathogeny of tic, the mental condition of tic subjects, the etiology, and pathological anatomy, study of the motor reaction, accessory symptoms, the different varieties of tics, tics of speech, the evolution of tics, antagonistic gestures and stratagems, the complications of tics, the relation of tics to other pathological conditions, the distinctive features of tics, diagnosis, prognosis, and treatment, including treatment by reeducation. There is a critical appendix by the editor, and the volume closes with a valuable bibliography. There is much in the work that will repay careful reading; and there are few practitioners who have not at some time or other been at a loss for the information contained herein.

Physicians' Manual of the Pharmacopœia and the National Formulary. An Epitome of all the Articles Contained in the U. S. P. VIII and the National Formulary. By C. S. N. Hallberg, Ph.G., M.D., Professor of Pharmacy, School of Pharmacy, University of Illinois, Member of Committee on Revision of the U. S. Pharmacopœia and of the Committee on the National Formulary, and J. H. Salisbury, A.M., M.D., Assistant Professor of Medicine, Chicago Clinical School. Chicago: American Medical Association, 1907.

This is a useful little book of reference for the busy practitioner who wishes to treat his patient on purely ethical lines, but is sometimes at a loss to know whether the use of a certain drug or combination of drugs is permitted. The book contains a list, with formula and brief description, of all the articles sanctioned by the Pharmacopœia and National Formulary. The latter book is one prepared by druggists for the guidance of physicians in the treatment of their patients, and which the National Food and Drugs Act has made a legal standard in company with the Pharmacopœia. The use of the book is facilitated by a therapeutic index and by a glossary of synonyms. It is interesting to learn from a study of the latter how many of the now accepted preparations were first brought to the notice of physicians under the guise of secret remedies and even quack medicines, to say nothing of ordinary proprietaries, and the thought is suggested that some of the latter, even of those now under the ban, may possess valuable therapeutic properties which might win for them admission to some future edition of the U. S. P. or N. F.

Society Reports.

NATIONAL ASSOCIATION FOR THE STUDY AND PREVENTION OF TUBERCULOSIS.

Third Annual Meeting, Held at Washington, D. C., May 6, 7, and 8, 1907.

(Special Report to the MEDICAL RECORD)

(*Concluded from page 33.*)

CLINICAL AND CLIMATOLOGICAL SECTION.

DR. GEORGE DOCK OF ANN ARBOR, MICH., CHAIRMAN.

Address of the Chairman.—Dr. DOCK, in his address, limited himself to a discussion of some of the problems that forced themselves on the attention of those who had to treat and study tuberculosis, as well as to instruct others to do the same. While under the impetus of the movement that had brought about this meeting a tremendous advance had been made in our attitude toward tuberculosis, and it was well to view the field and see whether the strategic positions were properly held and whether the most effective blows were being delivered at as many points as the forces available permitted, one apparent need was to enlarge our facilities for the treatment and education of early cases of pulmonary tuberculosis. Another, equally great, was the means and places for the treatment of tuberculosis patients, in any and every stage, near their homes. At the present time general hospitals and public institutions either had no room for such cases or had not the necessary facilities. Phthisiophobia had much to do with this state of affairs, and while it was not everywhere so severe and obvious as it was soon after the infectiousness of tuberculosis was first made known, it was still partly responsible for the fact that, with few exceptions, the tuberculous patient could not secure proper and adequate hospital treatment near his home at a price that he could compass. Quite as great as the need of facilities for caring for the tuberculous was the need of more perfect arrangements for study and instruction. In some cities, as in many of the private and a few public sanatoria, there were facilities for study by graduate physicians, but the instruction of undergraduates still left much to be desired. Sanatoria could not largely be used for teaching undergraduates on account of their distance in general from teaching schools, but dispensaries could be made to suit that purpose admirably if they had, as they should always have, proper rooms, sufficient laboratory equipment, and an adequate corps of physicians. For teaching the phenomena of the later stages, special wards or hospitals for advanced cases would be of equal value.

Report of the Committee on Clinical Nomenclature.—Dr. VINCENT Y. BOWDITCH of Boston, the chairman of this committee, in his report gave the results of the schema for the classification of tuberculous patients, which was adopted by the National Association in May, 1905. Briefly, the cases were classified under the term incipient, moderately advanced, far advanced, and acute miliary tuberculosis, and the results of treatment were classified under the terms unimproved, improved, arrested, apparently cured, and cured. The committee reported that in addition to the sanatoria and hospitals for consumptives in which the classification schema and the tabulation schema adopted by the National Association were already in use, it had been adopted by thirty three institutions during the past year.

Dr. LAWRENCE F. FLICK of Philadelphia said the report, even as modified by the committee, did not lay sufficient stress upon prognosis.

Dr. CHARLES L. MINOR of Asheville said he had used this method of clinical nomenclature in his private work since it was first brought out, and was very well satisfied with it. He thought it was adapted not only to institutional work, but also to private practice.

The discussion was continued by Dr. ALFRED MEYER of New York and Dr. EDWARD O. OTIS of Boston.

Report of the Committee on Medication in Tuberculosis.—Dr. ALFRED MEYER of New York, the chairman of the committee, presented this report. It was the result of the combined efforts of six members, including the chairman. Each member of the committee submitted his views in writing to the chairman, and the latter then collated and edited the data thus obtained into one combined report, and sent a copy for signature or correction to each member of the committee. From this corrected preliminary report the final report, as presented to-day, was obtained. The committee believed that no directly curative medication had yet been discovered, but that many drugs greatly improved the general condition by ameliorating different symptoms, and indirectly limited the extension of the disease or brought about fibrosis. In view of that fact, the committee deplored the prevailing tendency to ignore the use of drugs in tuberculosis, regardless of their character or the special indications in individual cases. The committee, in its report, first referred to creosote. This remedy, and its carbonate was perhaps prescribed more generally by the profession in tuberculosis than any other. The committee was not much impressed with the value of creosote, excepting in lessening the secretion from an accompanying bronchial catarrh. The routine administration was not advised, but in patients whose kidneys were healthy and whose appetite was increased by small doses (one to three drops) it might be of service in consequence of this latter effect. Ichthyol appeared to be but little used by members of the committee. There appeared to be considerable difference of opinion as to the value of iodine and its derivatives. Its use appeared to be much less frequent among physicians than among surgeons. Whereas one member dismissed it as of no service, another one believed it deserved the title of specific more nearly than any other remedy. The truth probably lay somewhere between these two contradictory extremes. Arsenic in the form of Fowler's solution, or arsenic and iron in combination, were of service if anorexia or anemia were present. Codliver oil was but little used by members of the committee, the food fats being substituted for it. A number of members of the committee attributed great value to strychnine. Tuberculin had been used by five members of the committee. There was general agreement that in properly selected cases and in proper doses no harm was done, and those who had used the remedy longest believed they had seen improvement in previously stationary cases, and open changed to closed tuberculosis. When any opinion had been expressed by a member of the committee in regard to antistreptococcic sera it had been one of skepticism as to their value. In speaking of symptomatic treatment, the report first referred to cough. For this symptom, in the vast majority of cases, no special remedy was required. The value of training and the use of the will in unnecessary coughing was pointed out, as was also the striking absence of coughing at institutions where this principle was inculcated. To prevent harassing cough at night, however, with its attendant sleeplessness, codeine or heroin was advised. Fever was mostly combated with the rest and air cure; night sweats with atropine, agaricin, zinc oxide, and camphoric acid; pleuritic pains and pleurisy, with strapping and, if necessary, small successive cantharidal blisters or tincture of iodine. For hemoptysis, when slight, glonoin or sodic nitrite, the dose to be determined by the blood pressure, which should be below 120 mm. of mercury; also aconite and atropine. Morphine should be given only when the bleeding was severe, and then preferably hypodermically with atropine. One member of the committee had the impression that not infrequently pneumonia resulted from a stoppage of the cough and the retention of the blood. Calcium chloride appeared to act about as well in small doses as in large ones, and the question arose whether it had any

hemostatic effect at all. Ergotin, although still recommended by Cornet, had been practically dropped. For diarrhea calomel was recommended, or, if it was of tuberculous origin, iodoform or ichthyol. For constipation, besides the usual cathartics, oil enemata at bed time deserved a more frequent use. For tuberculous laryngitis, insufflation of iodoform or orthoform. For ulcers, the application of lactic acid solution and frequent daily inhalations of weak formalin solutions. In many of these cases no treatment was recommended, excepting cocainization before mealtime.

Dr. Howard Fussell of Philadelphia said the report of the Committee on Medication in Tuberculosis took a safe, middle ground, and while it discouraged polypharmacy and over-drugging, it made a plea for the use of well tried single remedies which, in the experience of the members of the committee, had been of value. The speaker believed with the committee that no directly curative medication had yet been discovered, but he ventured the hope that the workers in the laboratory on the most attractive subject of opsonins, vaccines, and sera would in the relatively near future give us a substance that would enable us to cure a case of tuberculosis absolutely, instead of merely arresting it, as was now the case. Speaking of drugs, Dr. Fussell said that creosote and carbonate of creosote had been entirely disappointing in his hands, excepting that in small doses the remedy appeared to have a favorable effect upon the gastric distress which often accompanied tuberculosis, and which appeared to be more frequent now, when forced feeding was so much in vogue. He had found arsenic and iron most helpful in the anemic state, which was practically always present in advanced cases. Strychnine he regarded as the one drug of paramount importance in doses of 1-30 of a grain three times daily, and under its influence the heart was strengthened and the body musculature decidedly improved. Cough was best controlled by rest in the open air, but there came a time in many cases when codeine or heroin had to be used. Hemoptyses were best controlled by rest alone, but small doses of morphia, given hypodermically, would often allay the irritating cough which increased the bleeding.

Dr. Silvio von Ruck of Asheville, N. C., who was a member of the Committee on Medication, presented a minority report, in which he limited himself to the discussion of tuberculin. In properly selected cases and in proper doses tuberculin did no harm, but, on the contrary, was capable of accomplishing good. He especially wished to emphasize the fact that the occurrence of fever reaction of any degree was an indication of a therapeutic overdose, and while such reaction was the signal for an intermission between injections until the fever had subsided, it was better to avoid it entirely. The constitutional symptoms of a tuberculin reaction depended upon reaction in the local tuberculous areas, and it was the local and not the constitutional effect which was the best and safest guide in dosage. In the earlier stages, before there was marked catarrhal or cavernous phenomena present, it was not a difficult matter for one practiced in auscultation, by frequent examinations, to observe the effect of the remedy locally. Dr. von Ruck said that at the Winyah Sanatorium crude tuberculin was now seldom used, its place having been taken by various modifications, including those of Klebs, Hunter, and himself, and later by extractives of the bacillus itself. With the exception of Hunter's modification, these modifications had proved equally as effective, and some of them infinitely more so, than crude tuberculin, and they had the additional advantage of greater safety.

Dr. Edward O. Otis of Boston said that with dispensary patients and those in hospitals for advanced tuberculosis he had found codeine and heroin the two most efficient drugs for the purpose of allaying cough. To control night sweats he depended largely on agaricin and camphoric acid. In spite of the view that it was now considered almost heretical to use ergot in hemoptysis, he still believed it had some value in selected cases, using the blood pressure as a guide. He had in mind several cases of hemoptysis where ergot proved beneficial, in connection with a low blood pressure, where other remedies had previously been employed without avail.

Dr. Flick said he did not believe that nephritis was a contradiction to the use of creosote. He looked upon creosote as one of the most valuable remedies we had in certain forms of mixed infection, and in all advanced cases of tuberculosis the drug should be used in large doses. He had given it in fifty-drop doses, three times daily, for several years without intermission, in most advanced cases, in which he could not help but feel that the preservation of life and whatever restoration occurred was due largely to the creosote. Iodine he regarded as the nearest specific remedy we had against the tubercle bacillus itself. It should not be used by mouth, but by the skin. For over fifteen years he had used iodine by inunction, first as iodoform, and later as iodized oil. Sulphate of magnesia, in small doses, was the one drug which he had found of value in tuberculous diarrhea. He also referred to the use of fly blisters, not to relieve pain, but for the purpose of withdrawing serum, which was allowed to be reabsorbed by the patient.

Dr. Charles L. Minor of Asheville said he also used fly blisters, but not for the purpose suggested by Dr. Flick. He was satisfied that in incipient apical lesions the persistent use of fly blisters, once or twice weekly, was beneficial. They reduced the patient's temperature and might even have an actual physical effect upon the underlying lesion. The fly blister should be left on long enough to raise a good blister; then it should be removed, and the wound dressed in the usual way. He did not try to get reabsorption of the serum that was withdrawn.

Dr. F. M. Pottenger of Los Angeles said that in the treatment of cough he rarely used either codeine or heroin, preferring the use of the wet jacket. If this was properly made and applied it would relieve not only the cough, but also reduce the temperature and prevent night sweats. He was somewhat disappointed that the committee did not recommend hydrotherapy in connection with the fever of tuberculosis. For that purpose he used sponging with tepid water, which he preferred to cold water. In dealing with tuberculous diarrhea, he cleaned out the alimentary canal and prescribed a carefully selected diet. He believed that tuberculous laryngitis, taken early, had practically the same prognosis as tuberculosis in the lung.

Dr. Charles Denison of Denver said that in dealing with hemoptysis he had almost entirely discarded the use of drugs, preferring the mechanical method of strapping the chest, thus putting the affected lung at rest.

Dr. George Mannheimer of New York showed an instrument by which a patient could medicate his own larynx. It consisted essentially of an elongated medicine dropper, made of heavy glass and properly bent at the tip. The instrument could be employed for the injection of either watery or oily solutions. It possessed the advantage of being cheap, simple, and effective, and could be used by the patient himself.

Dr. Woods Hutchinson of California regretted that the report did not refer a little more radically to codliver oil as an article of food. As to night sweats, the older routine methods of treatment he considered irrational and unnecessary. Night sweats were the result of the collection of toxins in the system, and by keeping the patient in the open air and regulating the bowels and the diet the night sweats would disappear.

Dr. S. A. Knopf said that more stomachs had been spoiled by creosote than by anything else he knew of. It was absolutely unpardonable to give a man fifty drops of creosote three times a day. As for the specific value of the drug, he doubted it very much. He did not think there

was any specific in tuberculosis excepting tuberculin, and that had its limitations. In diarrhea, Dr. Knopf said he did not give any medicine at all. He cleaned out the intestinal canal and regulated the diet. Under this plan of treatment the patients usually did nicely; but there were certain diarrheas that we could not control without large doses of opium. When we were in the presence of a dying consumptive, he believed it was a sacred duty to give him morphine in doses sufficient to make him comfortable and relieve his distress.

Dr. Myer Solis Cohen of Philadelphia said that under the use of carbonate of creosote he had seen patients with mixed infection and fever improve, after months of fresh-air treatment night and day had failed to benefit them.

Report of the Committee on Mixed Infection in Tuberculosis.—Dr. Lawrence F. Flick of Philadelphia, the chairman of the committee, read this report. He stated that in the light of our present knowledge it was not practicable to draw up a report on mixed infection in tuberculosis which in all its details could be consistently indorsed by a committee of six men. There were many points upon which men agreed, and there were some points upon which they held personal views based upon facts as they saw and understood them. It was the opinion of the majority of the members of the committee that mixed infection in tuberculosis was a symbiosis of other microorganisms with the tubercle bacillus in the tissues of the body, either in the tubercle itself, or outside of the tubercle in the parenchymatous tissue, in intracellular tissue, in a mucous membrane or a serous membrane. The secondary microorganisms might fraternize with the tubercle bacillus, or merely coexist with it. It was possible that they might repress or stimulate the growth of the tubercle bacillus, and it might be that they had no effect upon it. Mixed infection played an important rôle in tuberculosis, and gave rise to the symptom-complex known as consumption. Pure tuberculosis was a disease with a low temperature range, with disturbance of the circulation out of proportion to the temperature, usually with loss of weight, fatigue, variation in mental attitude, disturbance of the vasomotor equilibrium, and excessive reflex activity. The symptoms of high fever, extremely rapid emaciation, excessive weakness and violent cough were due to mixed infection. The microorganisms that produced mixed infection, either by symbiosis with the tubercle bacillus in the tubercle itself, or by running a concurrent course in some other tissue of the body were the streptococcus, the staphylococcus, the pneumococcus, the influenza bacillus, possibly undiscovered microorganisms which produced colds, the diphtheria bacillus or pseudo-diphtheria bacillus, the colon bacillus, Friedlander's pneumobacillus, and possibly a number of other microorganisms the pathogenicity of which was not recognized. All of these microorganisms had been found in sputum, and some of them could be found constantly in the sputum of advanced cases. The staphylococcus, the streptococcus, the pneumococcus, the influenza bacillus, and the diphtheria bacillus had all been found in cavities in the lungs, in the lungs apart from cavities, and in other organs of the body after death. The pneumococcus, streptococcus, and staphylococcus had been found in washed sputum, and the pneumococcus and streptococcus had been found in the blood in hemorrhage of the lungs. The streptococcus had been found in miliary tubercles which had not broken down. Nearly all the microorganisms which had been named as playing a secondary rôle in tuberculosis had been found in the mouths of people apparently in good health.

Dr. J. S. Bullock of Silver City, N. M., in a minority report said that many years experience with tuberculosis had not served to give him any very definite ideas regarding the rôle of mixed infections. To say just where tuberculosis began and mixed infection left off, granting that such an entity as a mixed infection existed, he believed to be impossible in any given case. That mixed infections had a place he was prepared to admit, and one might almost say prove from the fact that tuberculosis of closed cavities, as for instance joints or the classic cold abscess, ran a practically afebrile course until exposed to air, which apparently gave rise to secondary infection. The same was true of nonulcerative pulmonary tuberculosis, closed cases. That pure tuberculosis could, however, give rise to all the phenomena that were ordinarily ascribed to mixed infection the speaker had no doubt. Granting the existence of mixed infection, it became impossible to say what organism or combination of organisms with the tubercle bacillus was causing the condition. An exception might be made in the very exceptional instances in which a brilliant result attended the use of streptolytic serum, when the cause was manifestly the streptococcus. This serum was rarely ever efficient during cavity formation, which fact was at least suggestive of the nonidentity of the streptococcus with cavity formation. That hemorrhages occurred without the aid of mixed infection, Dr. Bullock said he had not the slightest doubt, and the same was true of night sweats, fever, and every other symptom presented in tuberculosis. This was not affirming, of course, that other organisms did not sometimes aid the tubercle bacillus in its destructive campaign. Whether a mixed infection could occur without tangible evidence of its presence in the symptomatology of tuberculosis we did not know, nor were we able to recognize its presence either scientifically or practically. After all had been said, it seemed to him that we used the term "mixed infection" rather too glibly, and that tuberculosis was almost always the real enemy to be fought. It was certain that without tuberculosis we would not be discussing pulmonary infections other than those well known to us. We all knew and admitted the rarity, if they existed at all, of serious pulmonary infections running the course of tuberculosis of the lungs without the tubercle bacillus and its life cycle as a pathogenic foundation. Mixed infection was a convenient terminology for one of the generalizations of our art and science, so tempting to apply and partly explain one of the enigmas of tuberculosis, that we often used it to cover a really enormous ignorance of actual conditions. The real mixed infections we had to regard and care for were those well known to us all, namely, syphilis, influenza, and various other diseases, intercurrent and frank, which threatened the future of our tuberculous patients.

Mixed Infection in Pulmonary Tuberculosis.—Dr. Arnold V. Klebs of Chicago, in a minority report, said he could not see the causal correlation between certain symptoms in pulmonary tuberculosis and a "mixed infection" determined *intra vitam* by methods at present at our command, in the vast majority of cases. Attempts at explanation of certain signs and symptoms in the course of pulmonary tuberculosis by the activity of other microorganisms than the tubercle bacillus must be considered futile, and in no way had given information or assistance to the clinician as regarded the diagnosis, prognosis, and treatment of the disease. It could not be denied, however, that in certain cases, especially those with more or less extensive tissue destruction, the activity of certain other microorganisms, chiefly the pyogenic types, influenced the clinical picture. The exact clinical division of cases into such with or without "mixed infection," and especially the determination in these cases of the dependence of certain symptoms on the presence of definite species of bacteria seemed not possible at present. The two principal methods of clinical medicine which had been used for the recognition of mixed infection were the bacterial findings in the sputum and the determination of fluctuation of the body temperature. Personally, Dr. Klebs said, he had not been able to draw any valuable clinical conclusions from the presence or absence of bacteria other than the tubercle bacillus in the sputum, and he held that it was fairly well established, both clinically and experimentally, that the

tubercle bacillus (and its products) alone was capable of producing fever in various degrees according to its virulence. Furthermore, the variability of the type of fever was very largely dependent on the individuality of the patient.

Dr. W. L. DUNN of Asheville said the whole difficulty in connection with this question seemed to come from the attempt to reconcile the clinical features of tuberculosis with the bacteriological findings in the sputum. Personally, he had not been able to explain his cases by the bacteriological findings in the sputum, and he thought these various microorganisms must be considered in the sense of being secondary rather than symbiotic.

Dr. MINOR said he was satisfied that a mixed infection could and did exist in tuberculosis, but he had been unable to prove to himself that the sputum could give us satisfactory evidence of its existence. One of the beneficial effects of country air was that it did not add to the already existing mixed infection, and allowed that present to die out, and one of the great dangers of patients who had advanced to that stage of tuberculosis in which there were excavations was the probability of streptococcus reinfection when they returned to ordinary climates.

The discussion was continued by Drs. G. B. WEBB of Colorado Springs, KNOPF of New York, and S. VON RUCK of Asheville, and closed by Dr. Flick.

Some Experience with Tuberculin.—Dr. L. ROSENBERG of Bedford Station, N. Y., read this paper, giving his experience with the use of tuberculin at the Bedford Sanatorium of the Montefiore Home. He expressed the opinion that with the aid of tuberculin, judiciously administered, they had been able to obtain somewhat better results than with the ordinary methods employed, particularly in those cases that had advanced beyond the first stage of the disease.

Dr. LAWRASON BROWN of Saranac Lake said a careful review of the literature on the subject forced one to the conclusion that the evidence in favor of tuberculin was very slight in the vast majority of cases, and that it depended largely on personal opinion. The more the man used tuberculin, the more he was in favor of using it, but there was little proof to show that it did good. Undoubtedly, there were cases upon which it exerted a great influence, but there were others on which it exerted no influence whatever.

Dr. ALFRED MEYER of New York said that in spite of his belief in the data presented by Dr. Rosenberg, which were quite favorable to tuberculin, he was inclined to agree with Dr. Trudeau that we must be a little cautious in drawing conclusions, because of the kind of cases selected for this treatment. Let us use our hygienic and dietetic and hydrotherapeutic remedies, and so forth, and then, when the patients no longer continue to improve, let us try this or that drug, or this or that serum or tuberculin, and see if there is any additional improvement following its use.

The Varieties of Tuberculosis.—Dr. WOODS HUTCHINSON of New York stated that the subject of the varieties of tuberculosis was of immense practical and general importance. The current miliary, bronchopneumonic, and fibroid types were merely on a symptomatic basis. The first was merely an expression of an involvement of the blood stream, and was not a definite and characteristic type. The bronchopneumonic and the fibroid were often different stages of the same type, like the old "parenchymatous" and "interstitial" nephritides, the first representing the acute stage, which, if the patient survived, would pass on into the chronic or fibroid stage. The line of demarcation between these two types, was very uncertain. Dr. Hutchinson said he simply wished to call attention to one factor which, while it had been referred to frequently in a vague and general way, had never received the recognition to which it was entitled, namely, the factor of race and social condition, so far as the latter affected the life and habits of the class. During his residence on the Pacific coast he had come in close contact with a number of the Indian tribes living there on the reservations, and was struck by the fact that so many of the Indian children had scars on the neck or elsewhere, and showed other evidences of a strumous condition. He was informed by the physicians to the reservations that fully nine-tenths of the deaths among the Indians were due either to tuberculosis or gunshot wounds, the vast majority to the former. Not only among the Indians on the reservations, but also among the Alaskans and the Eskimos from 60 to 80 per cent. of the deaths were due to tuberculosis, and in a communication presented to the Association a year ago by Dr. James Walker, among the Sioux Indians 47 per cent. of the deaths were shown to be due to tuberculosis (24.4 per 1,000 living), a mortality eighteen times greater than the general mortality from the disease, and this among people who were living under favorable conditions as regarded food and open air. Dr. Hutchinson said this matter was also brought home to him by a visit which he was called upon to make in his official capacity as State Health Officer of Oregon to a group of tuberculous cases among the descendants of the French voyageurs who had settled near Portland. In that colony there was one house in which eight individuals had died of tuberculosis within the last six years. In another house, five deaths had occurred, and in another three. These people were apparently very susceptible to the disease, and the type was extremely interesting. Its dominant features were the enlarged glands, with crippling involvement of the bones and joints, and ulcerations of the cornea; in fact, it was a reproduction of the old-time scrofula, or King's Evil, which was regarded as such a scourge in Europe three or four hundred years ago. A similar frightful mortality he later found in a two years' residence in Southern California, among the Mexicans and Indians of the southwest. Dr. J. W. Brewer had investigated the Indian agencies of Arizona and New Mexico, and found that 72 per cent. of the death rate among them was due to tuberculosis. He had also observed among the pure American-born population of various regions of the United States a very virulent and rapidly fatal form of tuberculosis, especially among frontiersmen and their descendants, who had lost the immunity of the city dwellers. This might account for the comparatively high death rate from tuberculosis all over the United States. In contradistinction to this condition among races whose ancestors had not been exposed to tuberculosis, Dr. Hutchinson referred to the Jews, who had apparently acquired a high degree of immunity by continuous exposure to the disease. In the most densely populated tenement house districts of New York City, inhabited largely by Jewish people, the death rate from tuberculosis was strikingly low, averaging 163 per 100,000 living, whereas among the Gentile residents of the same districts it was 505 per 100,000 living. Similar contrasts in Chicago gave Jews 162; Gentiles, 502 per 100,000. In Philadelphia the Jewish death rate was 76.7, while that of the native white population was 205. per 100,000. While this striking immunity to tuberculosis among the Jews had been ascribed to the beneficial effects of the laws of Moses, Dr. Hutchinson said he did not coincide with that view. The laws of Moses were a mixture of crude rule-of-thumb hygiene and pure ceremonial, chiefly the latter, and had little to do with the case. Their system of meat inspection had no scientific basis, and all commissions on this subject had agreed that tuberculosis was rarely transmitted by meat. Living side by side with the Jews, in the same environment and under practically the same hygienic conditions, were the Irish and the negroes, with a death rate from tuberculosis of 645 and 531, respectively. The gradual acquirement by the Jew of a resistance to tuberculosis 100 times that of the American white, and 20 times that of the Sioux Indian, was a most encouraging fact in the campaign against the disease.

Dr. L. ROSENBERG said that much had been written in

regard to the immunity of the Jews to tuberculosis that was more or less of a dream. While it was a fact that the death rate from tuberculosis among the Jews living in the slums was lower than that among their neighbors, this was not because the Jews had acquired immunity—for most of them were recent immigrants from rural Russia and Poland where tuberculosis existed to a very limited extent—but because they were a sober race, whereas their neighbors, as a rule, were intemperate and dissipated. Otherwise, they possessed no immunity against the disease; they acquired it readily and succumbed to it readily.

Dr. Theo. Potter of Indianapolis said that in his experience the prognosis of tuberculosis was more unfavorable, on the average, among people who had been brought up in the country than it was among city dwellers. He ascribed this to the fact that an examination of the lungs of the city dwellers would almost invariably show more or less fibrosis, due to the constant inhalation of dust, from which the people living in the country were practically free.

Dr. Hutchinson, in closing, said the Jew of Europe was in the main a ghetto dweller, and while Russia showed a higher mortality from tuberculosis than any other country in Europe, the Russian Jew came to us with the lowest. He did not believe that alcohol had much to do with it. There had been a good deal of cant about the influence of alcohol upon tuberculosis, and it had proven a very convenient stone to throw at the dog. Alcohol or drunkenness was simply one of the subsidiary causes, and it did not account for the enormous discrepancy in the death rate from tuberculosis between the Jews and the Gentiles.

Phagocytosis in Sputum as a Measure of Resistance in Tuberculosis.—Dr. Albert H. Allen of Saranac Lake, N. Y., presented this paper, in which he offered the following conclusions: (1) Fifty-nine per cent. of the cases of tuberculosis showed phagocytosis when the phagocytic index was applied. Eighty-two per cent. of the cases showed phagocytosis when all cases showing phagocytosis at any time were included. (2) Phagocytosis in ordinary sputum examination seemed of little practical value in prognosis. In large groups of cases, certain features might be observed, *e.g.* phagocytosis was much less in his tuberculin cases. (3) From one autopsy, and from the variation observed, whether sputum was taken at intervals of minutes or months, it would seem that a specimen from the homogenized daily output was necessary for much accuracy. (4) Tuberculin reactions failed to produce positive and negative phases. (5) Phagocytosis seemed not to vary with the presence of bad symptoms. (6) Phagocytosis deserved a more extended study, especially since its importance in immunity was still undetermined. (7) Disintegrated tubercle bacilli, parallels, variation in staining—all seemed to be of no practical use in prognosis. This was in harmony with the literature.

Bacteriological Examination of the Feces as a Means of Early Diagnosis in Tuberculosis.—Dr. Myer Solis-Cohen of Philadelphia said the finding of tubercle bacilli in the feces of patients suffering from intestinal tuberculosis was not uncommon, but as a routine examination in cases of pulmonary or general tuberculosis, bacteriological examination of the feces was very little employed. Dr. Randle C. Rosenberger of Philadelphia had found tubercle bacilli in the feces of recognized cases of pulmonary tuberculosis, and also of patients who at the time of examination were not known or suspected to have tuberculosis in any form. A large percentage of these cases had since come to autopsy, and in but few were the peritoneum or intestinal tract involved. All showed evidence of tuberculosis in some portion of the body, many only in the lymphatic glands. The speaker then reported in detail six cases in which tubercle bacilli had been found in the feces. There was no family history of tuberculosis in any of these. One had pneumonia a year before admission. Another, three months before, had an attack of what was diagnosed as influenza. The previous medical history of the rest was negative. The duration of the illness from which the patients were suffering varied from two weeks to three years. Four of the patients suffered from diarrhea, one from chills, and three from muscle pains. Cough was not marked in any case, and was absent in four, although two of these had previously suffered from cough, and one developed it later. Three did not expectorate at all, and one only occasionally. When examined, the sputum in every instance failed to show tubercle bacilli. Two of the patients had suffered slightly from night sweats, and one complained of loss of weight. Hemoptysis had never occurred in any. There were no symptoms of peritonitis in any case. In one case examination of the lungs gave practically negative results. Two showed slight infiltration of one apex. One case presented slight consolidation of both apices; another, consolidation of the right apex with infiltration of the left. One patient who was thought to have tuberculous infiltration of the right apex, tuberculous pleurisy, and tuberculous ulcer, was found on autopsy to be suffering from general miliary tuberculosis.

SOCIOLOGICAL SECTION.

Mr. Paul Kennaday of New York in the Chair.

The Class Method of Treating Consumption in the Homes of the Poor.—By Dr. Joseph H. Pratt of Boston, Mass. This paper described in detail the work of the Emmanuel Church Tuberculosis Class, in Boston, which was organized in July, 1905. In an article published in the *Journal of the Outdoor Life*, the following September, the plan of treating poor consumptives by sanatoria methods in their own homes was outlined. The first report was published in February, 1906, in the Boston *Medical and Surgical Journal*, and the class method explained more fully. Recently a report was published by Drs. Hawes and Floyd of the work done in the Suburban Tuberculosis Class, which was formed in January, 1906. The latter was designed for those consumptives who lived too far from the city to be visited by the paid nurse of the Emmanuel Church Tuberculosis Class. In the Suburban Class the visiting was done by volunteers in the various towns and cities where the members lived. In this work, Dr. Pratt said, it was important that the classes should be small, as the doctor and the friendly visitor must establish close personal relations with each other. In the Emmanuel Church Tuberculosis Class the limit of membership was twenty-five. If more than this number were to be treated an additional class should be formed, as the work could be carried on most effectively in small units. Each class had its own directing physician and a paid friendly visitor, who devoted practically her entire time to the work. The cases taken into the class were those to whom other avenues of escape were closed. Either they were too poor or the disease was too far advanced for them to gain admission to the State sanatorium. Three advanced cases, rejected as unfavorable by the examining physician for Rutland, had recovered from the disease in this class and had been allowed to return to their work. In all fifty-two consumptives had been admitted to the class since it was started, nearly two years ago. The membership was confined to those in whom the clinical diagnosis had been confirmed either by finding tubercle bacilli in the sputum or by a positive tuberculin test. Deducting fifteen, the number of present members, thirty seven were left. Thirteen of these were in the third stage of the disease (far advanced tuberculosis) when they joined the class; three in this group had recovered and were now at work; seven had died. Of these seven, four were on the roll of the class at the time of their death; two were discharged for not conforming to the rules, and one was now too ill to attend the class.

There were fifteen moderately advanced cases. One of these was sent to Rutland in an improved condition; two had withdrawn from the class because they considered themselves well, although the disease was not arrested and the danger of returning to work was fully explained; one was unable to continue treatment on account of chronic joint disease; the remaining nine left the class with the disease arrested; in five of these it was apparently cured. There were also nine incipient cases. In seven of these the disease was apparently cured, and in the other two it was arrested. In other words, 75 per cent. of the twenty-four incipient and moderately advanced cases recovered. The average gain in weight was 25.2 pounds; the greatest gain was 60 pounds. The expenses of the class from July 1, 1904, to May 1, 1907, were about $2,000. The four chief factors in the success of the class had been: 1. The patients had spent the nights as well as the days out of doors. 2. They had been kept at rest in the recumbent position, not only until their temperature was normal, but until the symptoms of active disease had disappeared. 3. The system of daily records advised by Dr. Charles L. Minor of Asheville. 4. The weekly meeting. 5. Implicit obedience to the rules and regulations laid down. The class method had proved to be economical and efficient, and the speaker expressed the hope that classes would be established in cities where at the present time no systematic effort had been made to cure consumption.

Dr. Alexander M. Wilson of Boston said that while we must have sanatoria for early cases of tuberculosis and hospitals for the advanced cases, still along with our agitation for increased institutional provision for patients should go the perfecting of the tuberculosis clinic for the cases for which adequate institutional facilities could not be provided for years to come, and the home-class method, which Dr. Pratt had described, was the last and best development of the tuberculosis clinic. The day camp was another method of attacking the problem of the care of the tuberculous who remained at home. The first of these to be established was in Berlin, in 1900, rapidly followed by others in that city and throughout the empire, so that there were fifty such camps in Germany to-day. The value of the camp in educating a large number of advanced patients who had to remain at home, and in changing the habits of life of the patient's family, was inestimable. Neither the day camp nor the home class equaled the sanatorium in the supervision they afforded of the entire life of the patient, but each was recommended by its cheapness for a work that needed to be done for the patients who would not or could not go to a sanatorium. In the last analysis, the value of each of these methods doubtless lay in its service of education and prevention.

Dr. Walter L. Niles of New York described the general plan of the Christ Church Tuberculosis Class in New York City, which was essentially similar to that of the Emmanuel Church in Boston, with some necessary modifications, the most important of which was that, because of their environment, none of the members could sleep out of doors. There were no yards, verandas, nor areaways that could be utilized for that purpose in the crowded tenement-house districts where these people lived. Dr. Niles summarized the advantages of the "home sanatorium" treatment as follows: 1. It provided a satisfactory method of treatment for a large number of tuberculous patients who at the present time could not be treated in institutions. 2. It provided a satisfactory method of treatment at a minimum cost. 3. It afforded a detailed supervision of a small number of patients by physician and visitor, which resulted in accurate attention to details and, consequently, more satisfactory results. 4. Being cured or improved in their homes, patients were more likely to remain so, as they had learned to adapt the antituberculous life to their surroundings and would continue it. 5. It did not break up the home, which was so often necessary when patients were sent away. 6. Observation of cases was continued for a long time, and they were not required to return to heavy work as soon as the disease was arrested, but were gradually brought back to their limit of activity. 7. Because of the example which friends and neighbors saw as well as heard about, a wider and more important dissemination of knowledge regarding tuberculosis resulted. The only possible disadvantage which he saw was that by remaining at home patients might be subjected to worries and cares which they would not have to contend with in an institution. To relieve patients of such obstacles to recovery, however, was the special function of the friendly visitor, and a competent one could more than counterbalance any possible objection on that score.

Dr. Arthur K. Stone of Boston said the fundamental thing in the care of tuberculosis patients was the wise, constant, and persistent supervision of their daily life. Dr. Pratt had shown how private patients might be successfully managed in their homes. He had taken a selected group of difficult cases, and by his indomitable energy and enthusiasm had made his tuberculosis class a success. If he could do that with such inferior material, surely the general physician could find inspiration in treating similar private cases in their homes. It was obvious, however, that difficulties arose in the care of private patients. They could not be disciplined in the same way as could dispensary patients, and they were more firmly bound by conventions; but, on the other hand, there were obvious compensating advantages. The very successful classes conducted by Drs. Hawes and Floyd were a part of the out patient work of the Massachusetts General Hospital, and the background of their success was dependent on the existing machinery of that institution. The day camp that Dr. Wilson had described fully justified any expense that might have been incurred, as it was an object lesson to the hospitals of the city and of great educational value to the whole community.

Dr. Charles L. Minor of Asheville said he would take issue with Dr. Pratt about the necessity of continued rest until all activity of the disease had ceased. That seemed a rather indefinite term. A normal temperature alone would not indicate cessation of activity, because in many cases of tuberculosis we had no elevation of temperature. In some cases, where the pulse and temperature had fallen to normal, he thought carefully graduated exercises were advisable, especially among the poorer class of patients, who needed to build up a muscular force so that they could return to their work. Dr. Minor said the general impression should not go out that these patients could not be treated in their own rooms. A room with but a single window could not be ventilated, but with two or more windows properly placed excellent ventilation could be obtained.

Dr. Lawrence F. Flick of Philadelphia said that while the class method of treating consumption in the homes of the poor was not the most economical, it was the one most generally applicable, if introduced rightly. The best cure for tuberculosis was the home cure, because it was produced under conditions which would endure through life. When a patient had been cured in a sanatorium or away from home, it was sometimes a very difficult problem to again teach him a proper mode of life at home or anywhere else, and at the same time be a useful citizen; but the patient who had recovered under home conditions, and had step by step unconsciously learned the right life to live, was more apt to continue in that way, and that was the best result. Dr. Flick said the dispensary method, the class method, and the day camp method of treating tuberculosis were superior to the sanatorium method, in that they took care of the masses. There was one other, and that was the hospital method for dying cases, where the patient during the final stage of the disease was under absolute control, which was a most important factor in the prevention of tuberculosis.

Dr. Pratt in closing said that, broadly speaking, the lesson that the medical profession had yet to learn in the treatment of pulmonary tuberculosis was the benefit to be derived from rest. He had seen many patients harmed by exercise; he had never seen any harmed by rest.

Country Treatment of City Cases.—By Dr. B. H. Waters of New York. This paper gave the results obtained in 48 cases of pulmonary tuberculosis treated in suitable boarding houses in the country for a period of time varying from one to five months, and regularly visited by a physician. The conclusions arrived at by Dr. Waters were as follows: (1) That carefully selected, fairly early cases, placed in carefully selected homes, and kept under medical supervision, improved to such an extent as to be comparable to sanatorium patients. Certainly many of them in the same period of treatment would have done no better in sanatoria. (2) That certain cases, especially those of the first stage, had so improved as to be admissible, upon their return, to incipient sanatoria classes, having demonstrated, so to speak, their right to a further chance. (3) That the large majority of these patients had come back to the city improved in health, hopeful, and realizing the value of fresh air, quiet, rest, and food, knowing how to protect their families against infection, determined to do their part in the long struggle for health, and to help others. (4) That there was no danger of infection to others, or of the misuse of their own advantages by the patients themselves if they were carefully selected and efficiently supervised. (5) That only a small number of those suffering from tuberculosis were fitted for such country treatment, and of these a very much smaller number might safely take such form of treatment without medical supervision. (6) That the method was expensive ($7.78 per week per patient), and could only be used where special funds were available. It was quite possible, however, that the experience of last season would be of such value that by more careful management another year the cost might be materially reduced.

Dr. Flick said that he would feel a good deal of hesitation about sending a consumptive who was not properly trained out on a farm. The moment the consumptive was removed from the environment in which discipline was necessary, that discipline ceased unless he had been trained properly and had a full and complete understanding of the protection of others.

Dr. S. A. Knopf of New York said the patients referred to in Dr. Waters' paper were well instructed; otherwise, they would not have been sent to the country.

The chairman, Mr. Kennaday, said that many of these patients were very intelligent people, who had been in the hands of their physician for several months, and had been carefully instructed in regard to the danger of infecting others.

A Working Program for a Small City.—Dr. Oscar H. Rogers of Yonkers, N. Y., read this paper. The speaker said that whether the city in which a campaign was to be undertaken was a large or a small one, the problem in the fight against consumption resolved itself into: (1) The control of those who were now ill, so as to give these sufferers the best chance of recovery, and also, what was of still greater importance, so as to minimize the danger of infection to others. (2) The education of the people with regard to the disease to which they were all exposed, so that they might intelligently protect themselves against it. The first and most important step in a campaign against consumption was the formation of an efficient, concentrated organization. In Yonkers, N. Y., the movement was begun by organizing a Sanitary League which had for its object "the protection and promotion of the health of the people of Yonkers." All citizens interested were invited to become members, but the franchise was limited to those who contributed a small annual sum. The organization of the League was such that its affairs were administered and controlled by an Executive Council composed of a president, vice-president, a secretary, a treasurer, and twelve councillors or directors. From this Executive Council were chosen the chairmen of the standing committees, as follows: (1) On Laws and Ordinances; (2) On Water Supply and Drainage; (3) On Education and Publication; (4) On Relief; (5) On Hospitals; (6) On Statistics; (7) On Finance; (8) On Membership. Each chairman of a committee was empowered to select five associates, and was required to render to the Council at stated intervals detailed reports of the work done by his committee. After describing in detail the work of these various committees, Dr. Rogers said that as consumption was largely a house disease any system of control was inadequate which permitted case after case of the disease to occur in one house, while houses on either side, equally unsanitary in construction and condition, remained unaffected. Much of the high mortality was undoubtedly explained by the important circumstance that no provision nor special organization had ever been perfected for keeping track of the migratory cases—those cases which, having lived for a time in one house, moved to another, leaving infected apartments behind them, death traps for the unfortunate tenants who, all unconscious of the danger, succeeded them. If he were called upon to choose one single feature of an organization which would—in his judgment—be more efficient than any other in the fight against tuberculosis, he would choose that which kept track and control of the migratory cases. This was the particular work of a statistical committee. In the educational branch of the work physicians were of the greatest value. A course of popular lectures, for example, was more effective if given by the physicians of the community. In organizing a course of lectures care should be taken to see that they were made as attractive as possible. They should be illustrated, and for that purpose, and in order to limit to a certain extent both the length and subject matter of the lectures, a series of lantern slides should be prepared, a list of which should be furnished to each lecturer. In addition to this, each lecturer should be supplied with a set of pamphlets dealing in the simplest and most direct fashion with the various aspects of the subject. In the campaign in Yonkers, in which so much had already been accomplished, and in which the future was bright with still greater results, each speaker was furnished with fourteen monographs of this sort. They were also provided with a lantern and a set of slides, with gas tanks, and a potable frame on which to stretch the screen, and were prepared to go at a moment's notice to any part of the city and give a lecture. Of still greater value in the long run than lectures was the use of circulars of instruction, distributed at the time of the lectures and through other agencies, such as churches, public schools, societies, labor organizations, and the like. The most efficient single means of distribution was the public and parochial schools, the authorities of which had shown great willingness to assist in the good work. In Yonkers these circulars were printed in English, Italian, Polish, German, Slovak, and Yiddish. They preached fresh air, day and night; rest as much as could be had; food as much as could be taken. They also urged the importance of the early recognition of the disease. Casting about for some other way of appealing to the people, the Committee on Education and Publication hit upon the advertising lantern idea, and, having secured a suitable plant, various lantern scenes were given alternating with tuberculosis aphorisms. In the text of these slides, a certain amount of repetition was deliberately made use of, and each slide, as nearly as possible, was complete within itself. Some of the lantern slides had been criticised on the ground that they were pitched in a tone rather too optimistic. Dr. Rogers said that while this criticism was perhaps just, his own opinion was that we needed a lot of optimism in this work, and

that the element of hope was a most important factor in the fight.

The committee was now experimenting with another scheme of education. Through the courtesy of the telephone company they had secured permission to post notices on the telephone poles, and four bulletins, made of tin, had been prepared for that purpose. The texts were printed in colors, and the bulletins were so distributed as to reach the parts of the city where they were most needed. They had been criticised as vulgar, but the speaker confessed that he had little sympathy with such criticism. He believed that, for purposes of education, people did not "expectorate;" they did "spit," and if they were careless or inconsiderate in spitting, and needed instruction on the subject, the more direct and frank the instruction was, the more permanent its effect on their understanding. The following was an example of one of these tin bulletins: "Consumption is caused by the poison present in the consumptive's spit. The poisonous spit dries and goes as dust into other people's lungs. Don't spread the disease. Don't let others spread it. Spit into the gutter or into a spittoon." In whatever educational work was done, Dr. Rogers emphasized the fact that it was of the utmost importance to concentrate the efforts as much as possible upon the essential features; for example, upon the spitting nuisance; upon the importance of fresh air; upon the early treatment, and upon the avoidance of alcohol. Concentration was the keynote of success in educational work. But the real object of the campaign was broader than the education of the people generally; it was broader than the accumulation and publication of data regarding the disease. It was to get control of the disease, to limit its spread, and, wherever possible, to stamp out and destroy the sources of infection. This could be done only through a special dispensary organization. A tuberculosis dispensary, then, should be the goal of our effort: a place where the needy poor might receive the necessary treatment, and where all the interests and aspects of the disease were centered and kept under observation and control.

Mr. KENNADAY, in referring to other practical methods of disseminating facts regarding tuberculosis, referred to the use of the back of transfer slips that were issued on the street cars. Another important medium which had hitherto been largely overlooked was the public press. The papers, as a rule, were anxious to get this material if it was properly placed before them. Lantern slide pictures he also considered very effective in this educational propaganda.

Schools and Tuberculosis.—Dr. JOHN H. LOWMAN of Cleveland, Ohio, said it was less than ten years ago since the prophylaxis of tuberculosis in the schools had been seriously discussed. In 1899, Huebner, in a report on this subject, suggested that teachers as well as pupils in the schools should be under medical observation, and that one should not concern himself alone with the health of the scholars, but also with that of the teachers. Since that time there had been many contributions bearing upon this question by physicians, sanatorians, and educators, until now the school authorities themselves had taken up the matter practically, and were seriously considering the best way to protect the children. In order to control tuberculosis during the school age, it was necessary: (1) To discover through the records of the municipality and public institutions the children who were infected and those who lived in infected houses. (2) To examine and classify the individuals thus found, and place the contagious cases in sanatoria and the others in separate schools. (3) To develop the hygienic surroundings of these separate schools to the highest plane of excellence. (4) To specialize these children even during the vacations by referring them to the special consideration of outing societies. (5) To provide physicians who would at stated intervals examine the children and report to the supervisors the conditions found. (6) To use the utmost precautions for the protection of the teachers. (7) To introduce systematic courses on hygiene and tuberculosis into the curriculum of the schools. (8) Sanatoria for children. The difficulties to overcome were: (1) The examination of thousands of children in order to detect and classify those affected with tuberculosis. (2) Provision for the contagious cases in sanatoria for children. (3) Teachers for the classes of children with latent noncontagious tuberculosis. (4) Vigilant adequate supervision of the tuberculosis classes.

Dr. LINSLEY R. WILLIAMS of New York said that the New York Department of Health, in the examination of 90,240 school children from March 5, 1905, to the end of the school year of 1906, had found 1,039 cases of pulmonary disease (1 per cent). These examinations were made during the winter months, and without the removal of the children's clothing. In the examination of 2,295 school children of Manhattan, made at Sea Breeze, Coney Island, during the summers of 1905 and 1906, there were found 61 cases of pulmonary disease. Of these, 22 were cases of pulmonary tuberculosis. There were also 22 cases of tuberculosis other than pulmonary. These examinations were all made with the clothing removed.

Dr. JOHN J. CRONIN of New York said he thought too much attention was spent on the sanitation and ventilation and various other features of school life—which nobody regarded of more importance than he did—but it seemed to him that the one factor that we were trying to protect was the one that we neglected, namely, the school child itself. We paid no attention to the fact that the child was physically handicapped by being unable to breathe properly. After the removal of enlarged tonsils or adenoids, the change for the better that was observed in some of these children was frequently little short of marvelous. We should first try to make the child as near physically perfect as possible, and once that was done he believed that a great deal of tuberculosis would be eliminated from the schools.

Dr. S. A. KNOPF suggested instructing the teacher in the seemingly easy signs of early tuberculosis. The average school teacher was intelligent, and could be taught the objective symptoms of tuberculosis, especially those of early tuberculosis or the pretubercular stage. With teachers so trained, and with periodical examinations by skilled diagnosticians, he firmly believed that we would strike at the root of this evil.

The discussion was continued by Mr. KENNADAY and closed by Dr. LOWMAN.

The Detection and Treatment of Cases of Tuberculosis Among Factory Employees in Providence.—Dr. FRANK T. FULTON of Providence, R. I., presented this paper. He stated that for about a year he, in connection with others, had been engaged in an effort to detect and treat cases of tuberculosis among the workmen in some of the leading factories in Providence. It was thought that perhaps by engaging the interest and help of the management of some of the factories and mills, patients suffering from tuberculosis in a comparatively early stage, who were still actively engaged in their work, might be secured for treatment before the disease had entirely disabled them. The details of the scheme were decided on after considerable deliberation, the idea being to handle the matter in such a way that there would be no antagonism aroused on the part of the operatives. The movement was inaugurated by posting on the bulletin boards of the shops official notices stating that the management of the mill or factory had provided, without expense to the employees, a physician to examine anyone who had any suspicion that he might have tuberculosis, emphasizing the fact that in the very beginning the disease could be cured. The two establishments which took the matter earnestly were the Brown & Sharpe Manufacturing Co., which employed about 4,200 operatives, and the Wanskuck Woolen Mills, which em-

ployed about 1,000 operatives. From these two plants 34 operatives were examined during about ten months, 18 of whom were found to have tuberculosis, and were not under a physician's care. Some of the others had symptoms suggesting the disease, but no definite signs could be found. It was found that most of these men were living in a very unhygienic way, and their symptoms in several instances quickly disappeared upon their being advised how to live. Altogether, the work in connection with these two establishments have been very satisfactory, and while the number of cases treated had not been large, the speaker said he doubted if there were many sanatoria which would show a more marked improvement in as large a percentage of cases and in so short a time. The reason for this he certainly did not believe to be due to any advantage that the home treatment had over sanatorium treatment, but to the fact that the cases were detected before they reached an advanced stage. Whether the results obtained in the Brown & Sharpe Co. and the Wauskuck Mill would be obtained in many other establishments remained to be seen. The plan was entirely practicable, but would certainly fail unless some man in the management who was sympathetic, and who had the confidence of the employees, took an active, aggressive part. Originally, the plan was for the purpose of detecting and treating the disease, but Dr. Fulton felt sure that its greatest value had been educational. It had caught the interest and attention of wealthy, influential, and philanthropic business men, and at the same time brought the subject prominently before the laboring class.

Dr. Charles S. Millet of Brockton, Mass., in discussing Dr. Fulton's paper, said he had recently organized a campaign of a somewhat similar nature in one of the shoe factories of Brockton, and his experience would lead him to refer to one or two points which had not been sufficiently emphasized. One of these was the finding of the cases. Printed signs and circular letters would not answer for that purpose. It was necessary for some one to give his personal attention to the matter and seek out the cases at the bench, or else this plan of action would prove a total failure. It was also a good plan to call the superintendents together and describe to them the way in which the disease spread, what they could do towards preventing it, and how they could pick out the men who ought to be sent to the physician's office. This work among mill or factory hands must be done with extreme caution, and in a very unobtrusive manner, for even if a person is found not to have phthisis his fellow-workers were liable to shun and ridicule him if they learned that he had been subjected to an examination of the lungs. In order to find these poor victims, the foreman must be instructed to look for certain signs of tuberculosis, or at least of a debility which might or might not be due to the tubercle bacillus. For instance, any pallor of the skin which was so noticeable as to be discovered by a person who was not a physician must be deemed of enough importance to render a decision as to the presence of tuberculosis necessary. Another suspicious sign was emaciation; this might not be extreme nor accompanied by an appreciable loss of strength, and yet it was easily perceived, especially when it was of rapid onset. The third symptom which we should be on the lookout for was cough, and, although it might be insignificant in character, the reason for it must be determined, or else the physician had a right to conclude that he could justly ask the patient to submit to the tuberculin test. Osler had said that any cough which lasted over three weeks was very suspicious. The fourth and last symptom which must be sought for was hemorrhage. Many persons were prone to conceal a slight hemoptysis. Blood-spitting, no matter how small in amount, always demanded a careful consideration of all the sources from which the blood might come.

Mr. Frederick L. Hoffman of Newark, N. J., in a communication read by Dr. Charles O. Probst of Columbus, Ohio, said he had for many years taken an active interest in the problem of factory inspection, with special reference to preventive methods tending to reduce the liability to and the mortality from diseases of the lungs among men engaged in recognized unhealthy occupations. The facts were conclusive, fully sustaining the argument of Dr. Fulton, and emphasizing the necessity of an active propaganda for better factory conditions, using the term in a broad sense, and including workshops generally. Regardless of an earnest effort to diminish the mortality from tuberculosis, it was significant to find that the rate per 100,000 of population in the registration area of the United States was higher during 1905 than during 1902 and 1903. There had not been the anticipated decline in the death rate, and more so was this the case among men engaged in unhealthy trades or employments, especially those in which there was a constant and considerable inhalation of health-injurious minute particles of dust. Out of every 100 deaths from all causes, the deaths from consumption were among barbers, not quite 40; among bakers, 20; blacksmiths, 15; bookkeepers, 22; boot and shoemakers, not quite 13; cabinet makers, not quite 23; cigar makers, 28; clerks, 33; coopers, 25; drivers and teamsters, 22; dyers, 18; engravers, 25; file cutters, 50; flour millers, 15; machinists, 22; laborers, 19; jewelers, 30; harness makers and saddlers, 20; molders, 21; musicians, 13; peddlers, 23; painters, 15; plumbers, 22; printers, 28; rubber workers, 39; silversmiths, 29; stone cutters, 25; tailors, 12; wheelwrights, 20; upholsterers, 29; general textile operatives, 26. In contrast, out of every 100 deaths among agents, 8.5 were caused by consumption. Among carriage makers, 8; engineers and firemen, 10; teachers and professors, 6; merchants, 6; grocers, 8; physicians, 8; clergymen, 9, and farmers, only 6. Of course, the material differences in the age distribution in the different employments referred to had an important bearing upon the question, but it was safe to hold as a broad principle that wherever the number of deaths from consumption in the mortality from all causes exceeded 10 per cent., the conditions were such as to demand a careful and searching inquiry, and a deliberate program of sanitary reform.

Mr. W. A. Viall, the secretary of the Brown & Sharpe Manufacturing Co. of Providence, R. I., which was one of the institutions in which Dr. Fulton's experiments were carried on, said that in talking with other manufacturers who were anxious to undertake some work in this line, the feeling had been expressed that such measures might cause a certain amount of distrust among their employees, while others took the ground that it savored of paternalism. Personally, Mr. Viall said, he did not agree with those views; it was not paternalism, but protection, pure and simple, against an infectious disease. In order to obtain results, it was necessary to have a person in authority who was interested, one in whom the men had perfect confidence, and to whom they could go with the feeling that they would be treated sympathetically. Furthermore, it was necessary to select a physician who was interested in the work, and who had the ability to diagnose the cases and properly advise them. When the manufacturer and the physician were ready to cooperate in a hearty, sympathetic manner, results would be obtained that would be of lasting benefit, not only to the present generation, but to generations to come.

The discussion was continued by Mr. Christopher Easton of Pittsburg, Pa., and closed by Mr. Kennaday.

The World's Greatest Retail Drug Store.—The greatest drug store in the world is said to be found in Russia. It exists in Moscow, and is 203 years old. Its title is the Old Nikolska Pharmacy, and since 1833 it has been in the family of the present proprietor. It is a building of imposing dimensions, with many departments, including one of professional education for the staff, which numbers 700 persons. About 2,000 prescriptions are said to be dispensed daily.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NORTH CAROLINA BOARD OF MEDICAL EXAMINERS.

Morehead City, June 5-8, 1907.

CHEMISTRY AND DISEASES OF CHILDREN.

1. Define an atom. (*a*) How always found? (*b*) What is taken as the standard?
2. Define a symbol. (*a*) Also a coefficient. (*b*) What does each represent?
3. Define a metal. (*a*) How many are known? (*b*) Name the noted exception.
4. What is a thermometer? (*a*) How is it made? (*b*) Name standard brands.
5. What is a blood corpuscle? (*a*) How many kinds? (*b*) To what is the color due?
6. Define dentition. (*a*) At what age does it appear? (*b*) Name some of its disturbances.
7. What is ophthalmia neonatorum? (*a*) Whence derived? (*b*) Give treatment.
8. Define exanthematous fever. (*a*) Name three. (*b*) What ages are exempt?
9. What is diarrhea? (*a*) Acute inflammatory. (*b*) Treatment.
10. Define rachitis. (*a*) Who is most subject to it? (*b*) How long do the effects last?

PHYSIOLOGY AND HYGIENE.

1. Describe a complete physiological revolution of the heart; fetal and adult.
2. Give origin of salivary and gastric secretions and function of each.
3. Give function of pancreatic and intestinal secretions.
4. Through what media is the blood relieved of effete material and provided with new?
5. How is the blood current maintained and what arteries carry venous blood?
6. What is the function of the cerebellum?
7. If seventh cranial nerve were incised at its exit from the stylomastoid foramen, state briefly the result.
8. Give function of pneumogastric nerve as related to respiration.
9. Detail uses of the largest gland in the body.
10. What occupations cause a predisposition to pulmonary diseases?

ANATOMY.

1. Describe the pubic or pectineal bone.
2. Name the ligaments of the elbow joint (humerus with ulna and radius).
3. Give the relations of the deep palmar arch.
4. Name the divisions of fifth (trigeminus) pair of cranial nerves and mention in a general way the parts supplied by each (motor, sensory, etc.).
5. Give the boundaries of the inguinal canal.
6. Describe the cecum.
7. Name the contents of the submaxillary triangle and give its boundaries.
8. Mention the hepatic fissures, name the structures found in each and the lobes separated by each.
9. Describe the prostate gland (do not give its relations or its histology).
10. Name the structures cut in performing a tracheotomy above the isthmus of the thyroid.

N. B.—Answer only eight questions.

OBSTETRICS AND GYNECOLOGY.

1. Given: Primapara at end of eighth month of pregnancy, considerable edema of the face, feet, and legs, urine scant in quantity, slight cephalalgia, dimness of vision, anemic, weak, short of breath upon slight exertion; (*a*) give diagnosis; (*b*) what grave symptom might be expected to follow if patient is not properly treated; (*c*) briefly outline treatment.
2. During normal labor (*a*) how and by means of what action is the dilatation of the cervix brought about? (*b*) What forces are employed in the stage of expulsion?
3. Give diagnostic symptoms of placenta previa.
4. How would you treat a case of adherent placenta?
5. Prescribe for a case of pruritus vulvæ.
6. Name three causes for which you would curette the uterus, and state in which you would use the dull and in which the sharp curette.
7. In ventral fixation, (*a*) what organ is fixed, (*b*) for what purpose is it fixed, (*c*) to what (anatomically) is it fixed, (*d*) what kind of sutures should be used?
8. How would you treat a case of congenital atresia of the cervix?

MATERIA MEDICA.

1. Name and describe the methods of introducing medicine into the circulation.
2. Name an example of. (*a*) An alterative, (*b*) antiperiodic, (*c*) antispasmodic, (*d*) diaphoretic, (*e*) diuretic
3. Name the alkaloids of hyoscyamus—doses.
4. What are the uses of the bromides?
5. Name the preparations and doses of arsenic.
6. What is the dose of (*a*) ol. terebinthinæ, (*b*) tinct. veratrum viride, (*c*) Basham's mixture, (*d*) tincture of aconite, (*e*) caffeine citrate; (*f*) sparteine sulphate?
7. Why is atropine often combined with morphine when the latter is used?
8. Name three drugs most useful in the treatment of intermittent fever.
9. Write a prescription for an adult with bronchitis, containing three ingredients.
10. Criticise the following prescription:

℞ Argenti Nitratis.....gr. xx
Sodi Chloridi.....1 drachm
Aqua.....2 ounces

Sig. I drachm every four hours.

SURGERY.

1. Give symptoms and treatment of anal fissure.
2. Give diagnosis of strangulated hernia.
3. Give differential diagnosis between hydrocele and inguinal hernia.
4. Give diagnostic characteristics of syphilitic skin eruptions.
5. In hemorrhage of superficial palmar arch, which end of the bleeding vessel would you tie?
6. Give etiology of hydronephrosis.
7. Give diagnosis of mastoid disease.
8. Give indications for intubation of larynx.
9. In an injured elbow, what signs would verify fracture of internal condyle?
10. What conditions associated with loss of consciousness must be differentiated from traumatic intracranial lesions

PRACTICE OF MEDICINE.

1. Give symptoms of diagnostic value in the first and second week of typhoid fever.
2. Give differential diagnosis between primary lobar pneumonia and acute pneumonic phthisis.
3. Give causes and treatment of chronic dysentery.
4. Define leukemia, Addison's disease, myxedema, brachycardia.
5. Give symptoms and signs of aneurysm of the abdominal aorta.
6. Give symptoms of acute intestinal obstruction.
7. Give differential diagnosis between uremia, alcoholic coma, and cerebral hemorrhage.
8. Give definition and etiology of thrombosis in the brain.
9. Write one, and only one, prescription for chronic constination.
10. Describe the most important symptoms of cerebrospinal meningitis.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NORTH CAROLINA BOARD OF MEDICAL EXAMINERS.

Morehead City, June 5-8, 1907.

CHEMISTRY AND DISEASES OF CHILDREN.

1. An *atom* is the smallest quantity of an element that can enter into chemical action, or that can enter into the composition of a molecule.

(a) It is always found in combination with other atoms (either of the same or of different elements).

(b) The weight of an atom of hydrogen is taken as the standard for atomic weights.

2. A *symbol* is a sign by which an atom of an element is represented or expressed in chemical writing. It is generally the first letter or letters of the name of the element in Latin.

(a) A *coefficient* is a number placed before a chemical formula to denote how many times the formula is to be multiplied.

(b) *A symbol represents*:—(1) The name of the element; (2) one atom of the element; (3) the combining weight of the element as compared with hydrogen as unity; and (4) one volume of the element in a gaseous state

A coefficient represents the number of times that the formula is to be multiplied.

3. A *metal* is an element which is capable of replacing part or all of the hydrogen of an acid, to form a salt.

(a) There are between fifty and sixty metals.

(b) Mercury is an exception in that it is not a solid at the ordinary temperature.

4. "Thermometers are instruments for the measurement of temperature. They are usually glass tubes having a bulb blown at one end and closed at the other, the bulb and part of the tube being filled with mercury or with alcohol, whose contraction or expansion indicates a fall or rise of temperature. . . . In every thermometer there are two fixed points, determined by experiment. The lower, or freezing point, is fixed by immersing the instrument in melting ice, and marking the level of the mercury in the tube upon the glass when it has become stationary. The higher, or boiling point, is similarly fixed by suspending the instrument in the steam from boiling water. The instrument is then graduated according to one of three scales: the Celsius, or Centigrade, the Fahrenheit, and the Réaumur. The freezing point is marked 0° in the Centigrade and Réaumur scales, and 32° in the Fahrenheit. The boiling point is marked 100° in the Centigrade, 212° in the Fahrenheit, and 80° in the Réaumur scale. The space between the fixed points is divided into 100 equal degrees in the Centigrade scale, into 180° in the Fahrenheit, and into 80° in the Réaumur." (Witthaus' *Manual of Chemistry.*)

(b) Standard brands are:—Fahrenheit, Celsius, or Centigrade, and Réaumur.

5. A blood corpuscle is a minute solid body or cell, suspended in the liquor sanguinis.

(a) There are three kinds:—(1) Colored, or red corpuscles, or erythrocytes; (2) colorless, or white corpuscles, or leucocytes; of these there are five varieties: (a) small mononuclear leucocytes, (b) large mononuclear leucocytes, (c) transitionals, (d) polynuclears, and (e) eosinophiles; (3) platelets or plaques.

(b) The color is due to the hemoglobin in the red cells.

6. *Dentition* is the process of teething or "cutting the teeth."

(a) Primary dentition occurs normally between about the sixth and twenty-fourth months; secondary dentition occurs normally between about the sixth and twenty-fourth years.

(b) "The disturbances incident to teething may be divided into:

"1. *Local.*—The gums may be hot, painful, and tender. There may also occur a catarrhal stomatitis, with increased salivary secretions that, by dribbling, excoriate the chin, and may, by wetting the chest, cause a bronchitis.

"2. *Sympathetic or Reflex.*—Any of the following complications may occur: *Eye*: More or less severe inflammation. *Ear*: Catarrhal or purulent otitis media. *Digestive tract*: Gastrointestinal disturbances. *Respiratory tract*: Bronchitis, cough, etc. *Skin*: Erythema, urticaria, eczema. *Nervous system*: Restlessness, disturbed sleep, convulsions." (Gould and Pyle's *Cyclopedia of Medicine and Surgery.*)

7. Ophthalmia neonatorum is an infectious, purulent inflammation of the conjunctiva in the new-born.

(a) It is due to the gonococcus or some other pyogenic germ; and is produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc.

(b) *Treatment* is:—(1) Prophylactic—whenever there is the possibility of infection, or in every case, wash the eyelids of the new-born child with clean warm water, and drop on the cornea of each eye one drop of a one or two per cent. solution of nitrate of silver, immediately after birth. (2) *Remedial:*—Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a two per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

8. An *exanthematous fever* is a fever accompanied by an eruption on the skin.

(a) Scarlet fever, measles, smallpox.

(b) As a rule very early infancy and old age are exempt, but there are exceptions.

9. Diarrhea is a symptom of many pathological conditions; it is characterized by the fecal discharges being too frequent or too liquid.

(a) Acute inflammatory diarrhea is the above-named condition when due to some inflammatory process in the intestines.

(b) The treatment consists in withholding all food while the trouble lasts (but water must be given); castor oil or calomel should be given, this can be followed by bismuth subnitrate or chalk mixture. Milk feeding should only be resumed slowly and gradually, and can be preceded by beef juice or veal broth.

10. Rachitis is a constitutional disease of infancy and early childhood, characterized by defective nutrition with its chief manifestations in the growing bones.

(a) The most subject to it are the *artificially fed* children

(b) The effects last for a variable time, from some months to some years.

PHYSIOLOGY AND HYGIENE.

2. The *salivary secretion* is derived from the salivary glands (parotid, submaxillary, and sublingual).

Its functions are twofold:—I. *Mechanical:*—(1) to moisten the mouth, (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste, (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition.

II. *Chemical*:—See Question 3, below.

The *gastric secretion* is derived from the glands in the mucous membrane lining the stomach.

For function see Question 3, below.

3.

SECRETIONS.	ACTIVE PRINCIPLES.	FUNCTIONS.
Salivary	Ptyalin.	Changes starches into dextrin and sugar.
Gastric	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
	Trypsin.	Changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; in an alkaline medium.
Pancreatic	Amylopsin.	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.
Intestinal	Invertin.	Converts maltose into glucose.

4. The blood is relieved of effete material through the lungs, the liver, the kidneys, and the skin. It is provided with new material through the alimentary canal, the lungs, the liver, the lymphatics, the spleen, and the skin (by absorption).

5. The circulation of the blood is regulated in (a) *the arteries*, by: (1) the elasticity and tone of the arteries, (2) the force and frequency of the cardiac contractions, (3) the resistance in the capillaries; (b) in the *capillaries* it is regulated by: (1) the action of the heart, (2) the action of the arteries; (c) in the *veins* it is regulated by: (1) the action of the heart, (2) aspiration of the thorax, (3) the contraction of the muscles, and (4) slightly by the valves in the veins.

The pulmonary arteries carry venous blood.

6. The functions of the cerebellum are:—Coordination and equilibrium.

7. The facial nerve is the motor nerve of the muscles of expression, also of the platysma and the buccinator; it also supplies the muscles of the external ear, the stylohyoid, and the posterior belly of the digastric. Through the chorda tympani it is a nerve of taste and a vasodilator of the vessels of the submaxillary and sublingual glands.

Hence section of the nerve would cause abolition of these various functions; notably, facial paralysis would ensue.

"When it is paralyzed, the muscles of the face being all powerless, the countenance acquires on the paralyzed side a characteristic, vacant look, from the absence of all expression; the angle of the mouth is lower, and the paralyzed half of the mouth looks longer than that on the other side; the eye has an unmeaning stare, owing to the paralysis of the orbicularis palpebrarum. All these peculiarities increase the longer the paralysis lasts, and their appearance is exaggerated when at any time the muscles of the opposite side of the face are made active in any expression, or in any of their ordinary functions. In an attempt to blow or whistle, one side of the mouth and cheeks acts properly, but the other side is motionless, or flaps loosely at the impulse of the expired air; so, in trying to suck, one side only of the mouth acts; in feeding, the lips and cheek are powerless, and, on account of paralysis of the buccinator muscle, food lodges between the cheek and gums." (Kirkes' *Physiology.*)

8. The pneumogastric nerve carries impulses which stimulate the respiratory center to increased activity, and hence quicken the respiration; it also contains fibers which inhibit the act of inspiration, and increase expiration.

9. The largest gland in the body is the liver. The functions of the liver are:—(1) The secretion of bile, (2) the

formation of glycogen, (3) the formation of urea and uric acid, (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

10. The following occupations cause a predisposition to pulmonary diseases:—Earthenware makers, file makers, cutlers, workers in quarries, builders, bricklayers, stonecutters, bakers, glass blowers, players on wind instruments, millers, accountants, clerks, printers, glass polishers, wool and cotton spinners.

ANATOMY.

3. The deep palmar arch extends from the base of the first interosseous space to the base of the fifth metacarpal bone, and is about one finger's breadth nearer to the wrist than the superficial palmar arch is. It is covered by the superficial and deep flexor tendons, adductor obliquus pollicis, parts of flexor brevis minimi digiti and of opponens minimi digiti. It rests upon the adductor transversus pollicis, the distal extremities of the metacarpal bones, and the interossei muscles. It is accompanied by the deep branch of the ulnar nerve, and two venæ comites.

7. The submaxillary triangle *contains*:—Styloglossus and stylopharyngeus muscles; stylomaxillary ligament; external carotid, internal carotid, facial, posterior auricular, temporal, and internal maxillary arteries; internal jugular, facial, and submaxillary veins; facial, pneumogastric, glossopharyngeal and mylohyoid nerves; parotid, submaxillary and lymphatic glands.

It is bounded:—*Above*, by the lower border of the inferior maxilla, and a line from the angle of the inferior maxilla to the mastoid process; *below*, by the posterior belly of the digastric and the stylohyoid; in *front*, by the median line of the neck.

10. The structures cut in performing a tracheotomy above the isthmus of the thyroid are:—The skin, subcutaneous areolar tissue, sometimes the platysma myoides, the anterior layer of the cervical fascia (separate the sternohyoid and sternothyroid muscles of each side), deep cervical fascia, the trachea, also any veins that may be encountered.

OBSTETRICS AND GYNECOLOGY.

1. (a) Toxemia or uremic intoxication.

(b) Convulsions (eclampsia).

(c) All channels of elimination must be freely opened; the bowels, skin, lungs, and liver must all be actively set to work to help the disabled kidneys. Purgatives, such as calomel, aloes, and jalap, or a saline; warm or hot baths; plenty of water to drink; also milk, and diaphoretics; meats should be prohibited; abundant fresh air is necessary; and all waist bands and corsets should be removed.

2. (a) *Dilatation of the cervix* is brought about by:—(1) The contraction of the longitudinal muscular fibers of the upper part of the uterus which tends to separate the edges of the os; (2) the hydrostatic pressure of the bag of waters against the os during these contractions; (3) the softening of the cervix.

(b) The *forces* employed in the *stage of expulsion* are:—(1) The contractions of the uterus (which are the main factors, and are involuntary); (2) the contractions of the diaphragm and abdominal muscles.

5. The treatment of pruritus vulvæ consists in removal of the cause, if possible; cleanliness, fresh air, tonics, and general attention to hygiene; local applications of solution of bichloride of mercury, 1:2,000; or carbolic acid, 1:100; or lead and opium; dusting powders of bismuth subnitrate, calomel, or zinc oxide are also useful.

6. Curettage is indicated:—(1) For the removal of placental debris, (2) in hemorrhagic endometritis, and (3) for diagnostic purposes.

A dull curette should be used in (1) and a sharp curette in (2) and (3).

7. In ventral fixation, (a) the fundus of the uterus is fixed; (b) to make a firm and permanent union between the fundus of uterus and the anterior abdominal wall, to prevent prolapse; (c) it is fixed to the anterior abdominal wall; (d) silk-worm gut sutures are used.

8. *Congenital atresia of the cervix* can be treated as follows:—After all proper antiseptic and aseptic precautions, the patient, anesthetized, is placed in the lithotomy position; the cervical canal is then perforated with an aspirating needle, and afterwards with a sharp-pointed bistoury, and then stretched with dilators. The uterus is then washed out with an antiseptic solution, and the cervix packed with gauze for twenty-four hours. A plug or tube of hard rubber or glass can be worn for a few weeks to keep the newly made canal patent.

MATERIA MEDICA.

2. Example of (*a*) an alterative, mercury; (*b*) an antiperiodic, quinine; (*c*) an antispasmodic, amyl nitrite; (*d*) a diaphoretic, jaborandi; (*e*) a diuretic, caffeine.

3. The alkaloids of hyoscyamus are:—Hyoscyamine, dose gr. 1/128; hyoscine, dose gr. 1/128. Only the salts are used.

4. The bromides are used as nerve sedatives, to lower reflex activity, in epilepsy, to induce sleep, as anaphrodisiacs, in congestion of the brain, in delirium tremens, in diabetes mellitus, in vomiting of cerebral origin, and in the vomiting of pregnancy.

5. The preparations and doses of arsenic:—Arsenic trioxide, dose gr. 1/30; liquor potassii arsenitis, dose ♏iij; sodium arsenate, dose gr. 1/10; liquor sodii arsenatis, dose ♏iij; arsenic iodide, dose gr. 1/10; liquor arseni et hydrargyri iodidi, dose ♏jss.

6. The dose of (*a*) ol. terebinthinæ is ♏x; (*b*) tinct. veratrum viride ♏xv; (*c*) Basham's mixture ʒiv; (*d*) tincture of aconite ♏x; (*e*) caffeine citrate gr. ij; (*f*) sparteine sulphate gr. j, by mouth.

7. Atropine is often combined with morphine when the latter is used, for the following reasons:—(1) To prevent nausea and insomnia; (2) to intensify the effect of the morphine, and so a smaller dose may suffice; (3) to neutralize the effect on the pupils.

8. Three drugs most useful in the treatment of intermittent fever:—Quinine, calomel, and methylene blue.

9. *For bronchitis*:—

℞ Acidi hydrocyanici diluti ♏xxxij.
Syrupi pruni virginianæ
Aquæ camphoræ aa ʒij. Misce.
Sig: One teaspoonful every three hours.

10. In this prescription the two salts will form an insoluble compound, silver chloride; further the sodium chloride is the chemical antidote to silver nitrate; sodi should be written sodii; aqua should be written aquæ; 1 drachm and 2 ounces should be written ʒj and ʒij, respectively; and in the last line one teaspoonful should be written in place of 1 drachm.

SURGERY.

2. "The diagnosis of strangulated hernia presents in the majority of instances no especial difficulty. The general symptoms to which most importance attaches are the severe and persisting vomiting, the absolute constipation, and the marked constitutional depression. Of the local symptoms, the most important perhaps is the absence of impulse on coughing in the tumor. In obstructed or incarcerated hernia the most conspicuous symptoms are those of obstinate constipation. In inflamed hernia the local manifestations predominate over all others. In strangulated ruptures the constitutional symptoms are the most striking." (Treves' *Manual of Surgery*.)

3. In *hydrocele* the tumor begins in the scrotum and may ascend to the inguinal region; does not vary very much in size, except to steadily increase; is translucent; is dull on percussion; gives no impulse on coughing.

In *hernia* the tumor begins in the inguinal region and may descend to the scrotum; is very variable in size, and may be reducible, or disappear on lying down; is not translucent; is not dull on percussion; gives an impulse on coughing as a rule.

4. *Syphilitic skin eruptions* are characterized:—By not itching; by being of a coppery or raw ham color; by being painless; by polymorphism, macules, papules, pustules, etc., being present at the same time; by being generally symmetrical.

5. In hemorrhage of the superficial palmar arch both ends of the bleeding vessel should be tied.

6. The chief causes of hydronephrosis are:—(1) Congenital obstruction or twisting of the ureter; (2) compression of the ureter by an abdominal tumor or gravid uterus; (3) impacted calculus in the ureter; (4) twisting or kinking of the ureter due to movable kidney; (5) stricture of the urethra; and (6) enlarged prostate gland.

7. Mastoid disease is characterized by:—Rise of temperature (up to 104° F.), tenderness, and pain over the mastoid process, which may be remittent or persistent; redness and swelling over the mastoid; bulging of the posterior and superior auditory canal; if the periosteum is affected, the auricle is unusually prominent; there may be fluctuation if pus is present.

8. The *indications for intubation* are:—Laryngeal diphtheria, or intense dyspnea from some other cause; it has been found necessary in fracture of the hyoid bone and in laryngysmus stridulus.

9. In fracture of the internal condyle:—(1) If the internal condyle is held between the thumb and index finger it can be moved independently of the shaft of the ulna, and crepitus will be obtained; (2) if there is any displacement, the fragment of the internal condyle will be found *above* the level of the external condyle and the tip of the olecranon.

10. The following conditions with loss of consciousness are to be differentiated from traumatic intracranial le-

sions.—Apoplectic coma, alcoholic coma, uremic coma, diabetic coma, and opium poisoning.

PRACTICE OF MEDICINE.

1. Diagnostic symptoms of value in the first and second weeks of typhoid fever are:—The characteristic temperature curve, each evening showing a higher fever than the preceding; the rose colored spots on the abdomen; distended and tender abdomen, chiefly in the right iliac fossa; "pea-soup" stools; the Widal reaction; and the presence of the Eberth bacillus in the urine and feces.

2. The symptoms and physical signs of *lobar pneumonia* and *acute pneumonic phthisis* may be the same for the first eight or ten days; at this period the fever in *pneumonia* drops by crisis; whereas in *phthisis* the fever continues for some time longer and the patient gets worse; the sputum contains tubercle bacilli and elastic fibers, and instead of retaining the rusty color it becomes purulent and greenish.

4. *Leukemia* is a condition characterized by a marked increase in the number of the colorless blood corpuscles, and by enlargement and other pathological changes in the spleen, lymphatic glands, and bone-marrow.

Addison's disease is a rare condition characterized by some pathological condition of the suprarenal glands and the sympathetic nervous system, and in which the skin becomes bronzed.

Myxedema is a condition characterized by atrophy of the thyroid gland, mental dullness, sluggish movement, and thick speech.

Brachycardia is a condition characterized by abnormal slowness of the pulse.

6. The symptoms of acute intestinal obstruction are:—(1) Sudden, intense, localized pain, at first in paroxysms, later continuous; (2) early and persistent vomiting, which later becomes stercoraceous; (3) absolute constipation; (4) abdomen tender, distended, and tympanitic; (5) anxious countenance, cold and clammy skin, feeble and rapid pulse, and collapse.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Sept. 1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	October 7
Arkansas*	F. T. Murphy, Brinkley	Little Rock	October 8
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	Los Angeles	Dec. 3
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	October 1
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov'ber 12
Delaware	J. H. Wilson, Dover	Dover	Dec'ber 10
Dis. of Col'bia	W. C. Woodward, Washington	Washington	October 10
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov'ber 20
Georgia	E. R. Anthony, Griffin	Atlanta	October 8
Idaho	J. L. Conant, Jr., Genesee	Boise	October 1
Illinois	J. A. Egan, Springfield	Chicago	October 23
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	October 22
Iowa	Louis A. Thomas, Des Moines	Des Moines	Sept'ber 17
Kansas	T. E. Raines, Concordia	Topeka	October 8
Kentucky*	J. N. McCormack, Bowling Green	Louisville	October 22
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	October 15
Maine	Wm. J. Maybury, Saco	Portland	Nov'ber 12
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec'ber 3
Massachusetts*	E. B. Harvey, State House, Boston	Boston	Sept'ber 10
Michigan	B. D. Harison, 305 Whitney Building, Detroit	Lansing	October 8

THE ATTITUDE OF PUBLIC HEALTH AUTHORITIES REGARDING THE PRESERVATION OF MILK BY HEAT.

By R. W. RAUDNITZ, M.D.,

PRAGUE, AUSTRIA.

PROFESSOR AT THE GERMAN UNIVERSITY OF PRAGUE.

At the present time a perfectly sterile method of obtaining milk is impossible. We strive, just as the surgeons do, to keep out the pathogenic germs or to destroy them. But while a milk expert is almost always able to point out the microorganisms which make milk unfit for sale or diminish the value of butter and of cheese, the physician can only in individual cases trace diseases to contamination of milk. In the case of typhoid fever, indeed, this is quite frequently possible, one-fourth of the epidemics being traceable to this source; much more rarely is this possible in epidemic cholera and in diphtheria, while only exceptional cases of foot-and-mouth disease and of pleuropneumonia can be thus accounted for. It is likewise not yet decided whether the causative agents of the inflammatory affections of the milk ducts in cattle can produce disease in man, such as inflammations of the pharynx or of the intestinal canal, when they are carried over to him in the milk; while the question of transmission of scarlet fever through milk can be settled finally only when the cause of this disease has been discovered.

Individual prophylaxis quite suffices to prevent the possibility of such infections, the simple boiling of milk, such as is practised in our kitchens, sufficing to destroy these infecting agents; transmission of typhoid fever through milk has been observed only after the use of raw milk; for instance, the drinking of skim-milk practised by workmen in the bakeries. Epidemics of scarlet fever said to have been spread by milk have been reported only from countries where much raw milk is taken as food—England and Scandinavia, for example. Hamilton has shown, moreover, that such reports cannot withstand a careful critical examination (*American Journal of the Medical Sciences,* CXXX., 879). No one, however, is compelled to drink raw milk.

In the case of milk products such as whipped cream, butter, and cheese, the matter stands somewhat differently. The first of these, whipped cream, is one of the most dangerous articles of diet in the warm season, but as it can be made acceptable to the taste by the addition of sugar, when prepared from pasteurized soured cream, this delicacy, so important in fattening cures, may be safely enjoyed in this form. The agents that cause pure souring of milk are the most effective destroyers of the pathogenic germs, and we act in this case just as the farmer, who most effectively fights the tares that harm his grain by favoring the growth of their enemies. For the same reason butter and most forms of cheese are not dangerous. In most modern dairies the first article is made from pasteurized cream that has been soured by pure cultures of bacteria, while cheese is likewise manufactured from soured milk or is ripened after being made, in which case most of the pathogenic bacteria are likewise destroyed.

Accordingly, only the milk used for the feeding of infants need occasion concern. We have passed through the purely bacteriological epoch when a few enthusiasts thought it necessary to trace all nutritive and digestive disturbances of artificially-fed children to microorganisms; indeed, there are many more physicians now who trace the acute summer diarrheas, for example, rather to the gross and minute differences between raw woman's milk and boiled cow's milk, and explain the typical increase of such diseases during the hot summer months either by the increased amount of food taken because of increased thirst with a corresponding increase in the noxious material introduced, or by the lowering of resistance that may result from the exhausting and injurious effect of a midsummer in the city. There is, however, no evidence to warrant such interpretation of facts, though at the same time there are no experimental proofs to show that contaminated milk is indeed the cause of summer diarrhea, and we must be provisionally satisfied with indirect evidence.

Anyone who has toured the Austrian Alps knows that milk obtained from the dirty alpine farmhouses, where the cows stand knee-deep in manure, when eaten raw produces most severe attacks of vomiting and of diarrhea, accompanied by serious symptoms of poisoning; even after being boiled, indeed, it may produce diarrhea, while the milk of a neighboring farm, perhaps, that is kept clean and is provided with a centrifuge, is quite harmless even when eaten raw. This fact is well known to the mountain guides, and one of them once told me how, after hurrying, burdened with baggage, behind a couple of long-legged Englishmen, he at last compelled them to take more frequent rests by advising them to drink "pure alpine milk." On the other hand, every practising physician who can with me compare the period before and after Soxhlet's agitation and activity, will agree with Variot that when clean milk, pasteurized or sterilized soon after milking, is used, the diarrheas of the weaning period as well as summer diarrheas are hardly ever observed, provided, of course, that the number of the meals and the strength and quantity of the milk are made to correspond to the physiological needs of the infant. The completely artificial feeding of infants has likewise become very much easier to carry through nowadays, although indeed it has not yet reached an ideal stage. Were we satisfied with such observation and experience we could even at this point declare that clean methods of obtaining and preserving milk, together with pasteurization or sterilization, accompanied by proper attention to

physiological circumstances in each case, could protect us from summer diarrhea. But experience in other directions interferes with such conclusion at this stage.

The fact is that summer diarrhea has been observed even when pasteurized or sterilized milk has been used; it is to be added, however, that such cases have appeared in epidemics or under a certain combination of circumstances. Thus, I have not observed such cases in my own private practice when mothers prepared the food, using water and pasteurized cream from a dairy recommended to them, but I have seen them often enough in my consultation practice, when the milk of any dairy, or even the full milk of the dairy preferred by me, had been used. In my own patients such cases appeared in certain summer resorts where the farmers had no great respect for clean methods of handling milk, although I am sure that my patients prepared the food in the country in exactly the same way as in their city homes. From these facts I must conclude, what is indeed partly well known to us, that boiling, pasteurization, or the so-called sterilization of milk that has not been cleanly obtained or kept clean after milking, do not suffice to prevent summer diarrhea, either because the harmful agents are not surely destroyed by such methods, or because ample time has been allowed them to manufacture the poisonous products of their metabolism before such destruction.

At present we can only surmise the nature of these harmful bacteria, because we lack as yet evidence corroborative of the splendid research work of Brooker, the determination, namely, of the germs causing the various forms of summer diarrhea or of their toxins in the milk used by the patients. It is not yet decided whether Petruchky is right in tracing some of the cases to the streptococcus responsible for the mastitis of cattle; nor is the work so simple as in typhoid fever, for instance, where a well that has been responsible for an epidemic usually contains the contaminating organisms for some days afterward, for milk may to-day have been contaminated and have caused disease, yet on the morrow may be delivered again in a pure state. Moreover, the pathogenic properties of the suspected bacteria must at first be systematically tested on the young of animals, which has not been done as yet.

Accordingly, we are compelled to fall back upon statistical evidence in proof of our contention, just as statistics are used to show the efficiency of vaccination, of measures used to fight the spread of typhoid fever, and of diphtheria antitoxin. But up to the present time there is no such statistical material available; it should give us the number of cases of summer diarrhea where clean, pasteurized, or sterilized milk has been used, the number of such cases where plain milk has been used, and the mortality in the two classes of cases; the statistician, moreover, must not put too much faith in the fact that the milk used is sold under such names as "clean milk," and so on, for both German and American experience has shown that the name does not always correspond to the true condition of affairs in this case. Moreover, the cases diagnosed as summer diarrhea must be really proved to be such, for every possible disease may masquerade under this name, tuberculous affections of the intestinal canal for instance, which of course would render any useful statistics impossible. In Prague, for instance, I have proved to my own satisfaction by the use of Widal's test that typhoid fever is extremely frequent toward the end of the first year of life, and one cannot therefore hold the contamination of milk in the narrow sense of the word responsible for a great number of cases of diarrhea occurring in summer, as it is usually in Prague quite impossible to trace the source of the infection with the typhoid organisms.

We may now summarize what has been said above, in the following words: Summer diarrhea of infants is most probably traceable to the contamination of milk; at the same time, we are not sure how successfully the disease-producing agents can be combated by a later heating of contaminated milk. The reader sees, therefore, that I place the greatest stress upon clean methods of milking and of keeping milk, and the Dairy Show in Washington in the year 1906 has shown, among other things, that such methods are possible even on a very large scale. Accordingly, the testing of the purity of milk is of the greatest importance, and in the case of pasteurized and sterilized milk this is to be done by counting the dead and the living bacteria, and perhaps by estimating the amount of albumoses and of peptones present; these very methods, however, have not as yet been completely developed.

Without cleanliness any method of preserving milk, and especially the use of heat, may become dangerous. All such methods, including the cooling of milk at a low temperature, attack and destroy first of all the harmless acid-producing bacteria that indeed may even be useful to the digestive process, while the harmful germs, otherwise held in check by the first organisms, now grow only the more luxuriantly. According to Chester-Brown, the use of formaldehyde at room temperature proves to be an exception to this rule.

In addition, other disadvantages have been traced to the practice of heating milk, which, however, I consider of no great importance if no long-continued or repeated heating at a temperature above 75° C (167° F.) is used. The following are among such disadvantages: The destruction of enzymes favoring digestion; the loss of the gases of milk, especially of 90 per cent. of carbonic acid gas, which immediately renders a portion of the earthy phosphates insoluble; the latter, however, undergo splitting by the heat, even without the loss of carbonic acid gas, so that 5/12 per cent. of phosphoric acid and of calcium, as well as 4/32 per cent. of citric acid is precipitated. The soluble proteids—cow's milk contains about 0.3 per cent. of lactalbumin and lactoglobulin— are changed in character, undergoing some coagulation with the loss of sulphureted hydrogen alone and in combination with alkalies. Caseinogen* is dissociated upon the surface of the milk and on the sides of the container into casein and its bases, while at the same time its colloidal nature is changed, thus accounting probably for the diminution of viscosity; in superheating (above 110° C. —230° F.) the casein is still further split into products containing nitrogen and phosphorus, that have not as yet been exactly analyzed, while at such temperatures the milk sugar, and with it the milk itself, turn brown. The fat of the milk—the milk globules—undergoes least change; the globules run together in part, while lecithin (0.06 per thousand parts of milk) probably loses its fatty acids.

The list of chemical sins committed by pasteurizing or sterilizing milk is indeed long, but almost all conclusions drawn from them have remained unproved. It is true only of cooked milk, as of all other food products, that it loses a trifle—some 5 per cent.—in assimilation when compared to the raw product, the reasons for such loss not being known.

*The term is used by C. Fisch, *St. Louis Courrier of Medicine*, February, 1900.

It is probable, however, that infantile scurvy, Barlow's disease, may be caused by the exclusive use of milk heated repeatedly or for too long a time, although we do not know at the present time whether the change in the phosphates and citrates or the decomposition of casein is responsible for this. It is a fact, on the other hand, that in France only six children out of the 21,000 that were fed on the highly sterilized milk of the "gouttes de lait" were affected with scurvy, and that the great majority of infants fed on milk prepared according to Soxhlet's method enjoyed good health, though perhaps not so good as most breast-fed infants. We have, moreover, the fine animal experiments of Brüning, showing that sucklings fed on boiled milk from a different species developed better than others fed on raw milk of the same kind, which fact may be explained by the destruction of the harmful bacteria in the milk of the first series of cases.

To recapitulate once more, I conclude that the disadvantage of using heat in the preservation of milk (pasteurization) lies chiefly in the fact that the beneficent bacteria are destroyed, while the harmful bacteria may be preserved and may later proliferate, the other disadvantages being easily avoided. A Board of Health should therefore allow the sale of commercially pasteurized milk only on the condition that an uninterrupted control of its purity has taken place.

SIXTEEN YEARS' EXPERIENCE WITH TUBERCULIN AND WITH OTHER PRODUCTS OF THE TUBERCLE BACILLUS IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

By KARL VON RUCK, M.D.,
ASHEVILLE, N. C.

During the sixteen years that have elapsed since the introduction of tuberculin by Professor Koch, this remedy or similar preparations have been used continuously in most cases of pulmonary tuberculosis treated by me in the Winyah Sanitarium, in conjunction with the usual hygienic and dietetic methods and such symptomatic measures as appeared of advantage in individual cases. The results of this combined method have been communicated from time to time in the reports of the institution.

Owing to the opposition to tuberculin which, after a short period of its popularity, led to its almost entire abandonment, the specific method of treatment of tuberculosis has, until the last few years, made but little progress, and, although there have been individual observers who, like the author, believed they derived material aid from the so-called combined method, their influence was inadequate to remove the early adverse judgment to a sufficient degree to reopen the subject for consideration.

It is not my purpose to examine in the present paper all of the causes which led to the abandonment of tuberculin in 1891, but a careful study of the early literature can leave but little doubt that, but for the pathological demonstration of Professor Virchow before the Berlin Medical Society in January and February of that year, the panic-like fear that followed the optimistic attitude prevalent before would never have taken possession of clinical observers who had tested its value and had expressed themselves on the whole in its favor.

I find that the early official reports of the directors of the German University Clinics and the reports from private sources prior to Virchow's demonstrations, were almost without exception indicative of a curative action of tuberculin in a majority of the cases in which it had been employed, and believe that I am conservative in stating that even at that time the favorable outnumbered adverse experiences in a proportion of five to one.

It was the influence of Virchow that for the time being decided the fate of tuberculin, and it is in my judgment another instance in which clinical judgment and observation deferred to the pathological anatomist to a degree unwarranted by the evidence. While Virchow admitted frequently that autopsies had shown nothing that could not have occurred in the course of the disease, apart from the influence of tuberculin, and stated repeatedly that he was not opposing the remedy, but that his demonstrations had no other object than to show that certain complications were found more frequently in cadavers of persons who had received tuberculin injections, and thereby that the remedy was capable of inducing most serious pathological alterations, he did not, as he well could have done, point out also that in the majority of these instances the autopsy showed far advanced lesions and complications which must have existed prior to the administration of tuberculin, and which in themselves would have precluded the expectation of a favorable influence from any remedy or method of treatment whatever.

Had Virchow opposed the selection of such hopelessly advanced cases, and had he further brought the acute pneumonic complications and other unusual findings into relation to the administration of the then customary large doses which caused the inflammatory reactions, much good could have resulted, for his findings were most valuable object lessons in showing that tuberculin, like other powerful remedies, was also capable of doing harm.

That curative effects were not likely to be shown in autopsies upon cases of advanced and complicated phthisis after a few weeks of treatment was pointed out by B. Fraenkel, in the discussion of whose paper these demonstrations were made; and many others who took part in it likewise called attention to this fact, and demonstrated patients showing unmistakably great improvement and apparent cures. Virchow, however, opposed all such clinical evidence, and on one occasion when the healing of tubercle in the larynx under the use of the remedy was claimed upon clinical grounds, he went so far as to reverse his previous teaching, by denying the possibility of the healing of tubercle without previous caseation and exfoliation, and he apparently paid no attention when, at a subsequent meeting, the microscopical specimens of the excised tissue were demonstrated for the purpose of showing the fact in the case in question.

When this prolonged discussion was finished, the supporters of the remedy had been reduced to a very few, even in the society where it occurred, and the lay and medical press had spread doubt and fear throughout the civilized world to a degree that practically eliminated the further favorable consideration of tuberculin.

In the foregoing reference to Professor Virchow, I would not be understood as underestimating the great services of this illustrious man to medical science, including the subject of tuberculosis. Although this was the second time in which his attitude and influence became obstructive to progress of the study of tuberculosis, there was in either instance an element of truth for his support. As with the question of the relation of caseous processes and of scrofula to tuberculosis, and its final settlement by the discovery of the tubercle bacillus by Pro-

fessor Koch, by which Lannec's teachings were practically restored, so in the present instance it required the discovery of specific immune substances in the blood of treated patients to rehabilitate tuberculin in the treatment of tuberculous disease. Having myself profited from Virchow's personal instruction, and sharing in the general admiration and love for the man as well as for the teacher, I detract nothing from his fame by showing that even a great man like him could fail to see all the truth when the subject was examined from a limited point of view.

During the years since passed, specific treatment of tuberculosis has, however, not been entirely abandoned, although those who have adhered to it from the beginning are few in number. The method made occasional new friends and their number has grown more rapidly of late. The literature now is again growing voluminous with contributions, this time almost without exception favorable to a combined method of treatment, in which the specific part with products of the tubercle bacillus is given an important place. In the meanwhile improvements in preparations and in the method of administration have also been made, and a better understanding of their action and of the selection of suitable cases has enabled those who have availed themselves of their use to improve their clinical results to a degree that speaks unmistakably in favor of their value.

The present renewed interest may perhaps justify a general review of my own work, which in years of observation and in point of number of cases treated is sufficiently ample to compensate for variation of clinical material and natural statistical differences.

The total of 1,893 cases treated and reported to January 1, 1907, represents all stages. Only such cases were excluded in which the prognosis had become practically hopeless by reason of the advanced stage of the lung affection or of its acute character, or of complications which precluded the prospect of a therapeutic result. Cases treated for less than one month were not reported.

The total results obtained with the various preparations as they appeared at the time of the patient's discharge were: Apparently cured, 904, or 47.8 per cent.; improved,* 718, or 37.9 per cent.; failed, 271, or 14.3 per cent.

A division of the cases according to the particular preparation employed shows for the original tuberculin in 379 cases:† Apparently cured, 135, or 35.5 per cent; improved, 142, or 37.5 per cent.; failed, 102, or 27 per cent.

Modifications of tuberculin in 348 cases: Apparently cured, 132, or 38 per cent.; improved, 107, or 48 per cent.; failed, 49, or 14 per cent.

Watery extract of tubercle bacilli in 1,166 cases: Apparently cured, 637, or 54.6 per cent.; improved, 409, or 35.1 per cent.; failed, 120, or 10.3 per cent.

The cases of the last series were treated and discharged since 1897, and to show better the character of the clinical material with the respective results in the different stages, their separate statement may be of interest, the more so, as this preparation is derived from the bodies of tubercle bacilli, whereas tuberculin and its modifications are made from the liquid media upon which they had grown, the bacilli having been removed by filtration.

*Under improved cases are included all such in which a complete cure was not attained, but in which the disease had become arrested or the local condition materially ameliorated, and the general condition, including subjective symptoms, had become decidedly better.

†An additional number of about 150 cases treated with the original tuberculin cannot be included, the records having been destroyed by fire.

	First Stage, 214 *Cases*	*Second Stage,* 484 *Cases*	*Third Stage,* 468 *Cases*	*All Stages,* 1166 *Cases*
App. recover'd	201 or 93.0%	305 or 63.9%	131 or 28%	637 or 54.6%
Dis. arr'st'd or greatly imp'd	9 or 4.2%	125 or 25.8%	117 or 25%	251 or 21.5%
Improved.....	4 or 1.9%	51 or 10.5%	103 or 22%	158 or 13.6%
Failed.....	None	3 or 0.7%	117 or 25%	120 or 10.3%

For the purpose of comparison with this last series of 1,166 cases there are available through the courtesy of a large number of other physicians the results obtained by them in a total of 2,183 cases, all of which had been treated with the same preparation and during the same period of time.

Since none of these cases have been published independently, and as I can here deal only with the general results, I beg to refer the reader to a fuller consideration and tabulation under the names of individual observers, which appeared in a separate publication.*

The results in the 2,183 cases of pulmonary tuberculosis referred to were stated as follows:

	First Stage, 748 *Cases*	*Second Stage,* 680 *Cases*	*Third Stage,* 746 *Cases*	*All Stages* 2183 *Cases*
Recovered..	625 or 83.5%	363 or 52.7%	110 or 14.8%	1098 or 50.3%
Dis. arrested.	43 or 5.6%	91 or 13.2%	93 or 12.5%	227 or 10.4%
Gr'tly imp'd..	49 or 6.5%	71 or 10.3%	113 or 15.1%	233 or 10.8%
Improved....	25 or 3.3%	59 or 8.6%	95 or 12.7%	179 or 8.2%
Failed.....	6 or 0.8%	105 or 15.2%	335 or 44.9%	446 or 20.3%

Among these cases were 921 in which the treatment was applied in special institutions and hospitals, the results of which it may be of interest to state separately, to show the difference between them and those obtained in private practice.

Results in 921 cases treated in special institutions and hospitals:

	First Stage, 300 *Cases*	*Second Stage,* 279 *Cases*	*Third Stage,* 342 *Cases*	*All Stages,* 921 *Cases*
Recovered...	285 or 95.0%	186 or 66.7%	64 or 18 7%	535 or 58.0%
Dis arr'st'd or greatly imp'd	11 or 3.6%	32 or 11.4%	98 or 28.6%	142 or 15.4%
Improved....	4 or 1.4%	8 or 2.9%	25 or 7.3%	37 or 4 0%
Failed	None	53 or 19.0%	155 or 45.4%	208 or 22 6%

Results in 423 cases treated in general practice at the patients' homes:

	First Stage. 153 *Cases*	*Second Stage,* 124 *Cases*	*Third Stage,* 146 *Cases*	*All Stages,* 423 *Cases*
Recovered....	130 or 85.0%	56 or 45.1%	19 or 13.0%	205 or 48.5%
Dis. arrested..	14 or 9.2%	24 or 19.4%	14 or 9.6%	52 or 12.3%
Greatly imp'd.	7 or 4.6%	25 or 20.1%	21 or 14.4%	53 or 12 5%
Improved.....	2 or 1.2%	3 or 2.4%	21 or 14.4%	26 or 6.1%
Failed.....	None	16 or 13.0%	71 or 48.6%	87 or 20 6%

Of special interest appear the results obtained in the last series of 423 cases treated by the family physicians in the patients' own homes, and therefore without otherwise desirable climatic or institutional advantages. The specific treatment was applied by 68 general practitioners who were, as a rule, without previous experience, and who, as far as I know, make no claim to more than ordinary skill in tuberculosis work. That the results are remarkable and of the greatest encouragement is at once evident, and if further substantiated by others and eventually by greater numbers of cases, we may hope that we are approaching a time when the mortality from phthisis will be reduced in an appreciable degree.

I am not unmindful that in the statistics so far considered the results were believed to have been accomplished when treatment was discontinued. The future course of discharged cases and the permanency of the results as a final measure, give, how-

*A Clinical Study of 203 Cases of Pulmonary Tuberculosis, etc., by Karl von Ruck and Silvio von Ruck, Asheville, N. C., 1897.

ever, also much encouragement to the view that the addition of specific methods to others of general value is of utmost importance.

The reports by the physicians who treated the 2,183 cases referred to are almost unanimous in the statement that in cases discharged as cured or arrested no relapses have been observed, and this statement by practitioners who treated their cases at home is particularly of value, since most, if not all, of their patients remained under their further observation after completion of a treatment to the date of their reports.

An inquiry as to the permanency of my own cases reported from 1897 to the close of 1904 was completed on December 31, 1906. It included all patients who had been dismissed from the institution with a clinical result of either apparent cure, arrestment, or material improvement.

Circular letters with detailed questions which were deemed essential to be answered were sent to 777 patients; from 602 replies were received, and the results are tabulated below:

without relapse was claimed by 414, or 68.8 per cent.

First stage.—Of 171 cases treated in the early stage were traced 139, or 81.2 per cent. Of the 139 had been dismissed as apparently cured 132. Six have since died, two from other causes than tuberculosis; six have relapsed but are still living; and 120 claimed to have continued in good health. Four cases had been discharged as greatly improved, and 3 as improved. All 7 cases were further treated at home and are living, claiming to be in good health.

This gives for this stage 127, or 91.4 per cent. without relapse, the patient living in good health for periods of from two to ten years.

Second stage.—Of 350 cases treated in the second stage were traced 265, or 75.7 per cent. Of 186 dismissed as apparently cured 15 have died; 4 deaths were from other causes than tuberculosis; 12 have relapsed but are still living; 159, or 85.4 per cent., continue in good health. Of 55 dismissed as greatly improved 6 have died of tuberculosis, 7 have re-

In regard to the final results in cases that had originally been reported as improved only, it should be stated that most of them were further treated by their family physicians under such directions as we deemed essential and which included the continuance of the specific remedy. A number of such patients returned once or oftener to the institution for a stay of a week or two for necessary examinations and further advice, and, although eventually brought to a more favorable state of health, I have not changed the classification of results originally reported since they were accomplished under the care of others; the fact that these patients have not grown worse since being all that I wish to show.

The table shows that of the original number of 873 patients, 96 failed to obtain improvement; all of them belonged to the far advanced and prognostically most unfavorable class. It was not a part of the inquiry to find out what become of them, because subsequent improvement, in case it should have occurred, could not be claimed for the treatment at my hands.

Of 602 cases traced, 476 were living, or 79 per cent. Relapse had occurred in 62, or 10.2 per cent., and 126, or 20.9 per cent had died. Good health lapsed, 42 are living and in good health. Of 24 cases discharged improved, 10 have died of tuberculosis, 2 have relapsed and are living; 12, or 50 per cent., continue in good health. We have, therefore, 213, or 80.4 per cent., of enduring results for the second stage.

Third stage.—Of 256 cases treated in the third stage, were traced 198, or 77.3 per cent. As apparently cured had been dismissed 82 patients; 22 have since died, 3 died of other causes; 16 relapsed and are living; 41, or 50 per cent., are living in good health. As greatly improved, were dismissed 62 cases; 22 have died of tuberculosis, 14 relapsed; 26, or 42 per cent., are living in good health. As improved, were dismissed 54 cases; 42 have died of tuberculosis, 5 have relapsed and are living; 7, or 13 per cent., are living in good health.

Thus, of 198 patients who came under treatment in the third stage and obtained a clinical result, 74, or 37.4 per cent., are still living in good health.

The favorable influence of specific remedies upon the tuberculous complications in the material of the Winyah Sanitarium has been pointed out from time to time in the several reports; and the influence observed by the physicians who personally reported to

me upon their cases is not at variance with that shown by myself.

Taking the entire clinical material here considered, we have a total of 4,076 cases in all stages treated by myself and over one hundred other physicians, which on their discharge had been classified as follows: Apparently cured, 2,002, or 49.1 per cent.; arrested, greatly improved or improved, 1,357, or 33.3 per cent.; failed, 717, or 17.6 per cent.

When we compare these results with such that are obtained by the hygienic and dietetic plan of treatment alone or in combination with climatic and sanatorium influences, the advantages in favor of the addition of specific remedies are so greatly emphasized that variations in clinical material and other coincidences are insufficient to account for the difference.

It was the observed difference in my own cases that caused me to adhere to the specific method from the period of its first introduction, and I may here remark that of my first series of 25 cases treated with tuberculin and reported 16 years ago, and of which only 5 cases belonged to the early stage, 10 patients are still living at the present time.

In the early part of this paper I have pointed out that tuberculin was abandoned in 1891 chiefly because of the danger that attended its use, and which with the mode of administration and bad selection of cases at that time was undoubtedly a matter for serious consideration. The question of danger has since been eliminated by improvement in clinical methods, by better preparations and by a more conservative selection of patients.

For myself I am able to say that I have for many years observed nothing of an adverse influence and have had no occasion to regret the administration of even a single dose. This appears to also be the experience of the physicians who reported their cases to me; in not a single instance was my question as to safety answered other than in the affirmative. The fact that among them were 68 general practitioners without previous experience in specific treatment, and that they likewise concur in this view, should remove any lingering fear of danger liable to be incurred, and in view of their clinical results it would seem that the method may with advantage be adopted by the profession at large.

It has of late been asserted that for the successful application of specific remedies in tuberculosis it is essential that each dose be controlled by observation of the so-called negative and positive phase of the opsonic index. Were this to be the case, the benefits of the treatment would have to remain limited to comparatively few patients, and the method would need to be confined to special institutions, hospitals, and experts, who command the necessary laboratory facilities. But the results obtained, as here shown and those reported by other observers, long before Prof. Wright introduced his method, indicate that fortunately this is not the case.

I nevertheless consider such studies and investigations as important and essential for the elucidation and improvement of the practical side of the subject. So far they have proved to me of service chiefly in demonstrating the action and the comparative value of different preparations. They have enabled others and myself to show that the products of the tubercle bacillus act in a truly specific manner by inducing active antibacterial or antitoxic immunity, the former occurring chiefly under the use of preparations which contain the tubercle bacillus substance, either in emulsion or in solution, and the latter under the use of the metabolic products of tubercle bacilli contained in the old tuberculin.

In active antibacterial immunization, specific amboceptor for tubercle bacilli can readily be demonstrated in the blood serum of treated patients by the hemolytic method of Gengou and its increase in relation to that of specific agglutinins and precipitins is now being observed and studied in my laboratory. While by these studies the specific treatment of tuberculosis has finally been established upon a scientific as well as a clinical basis, it is proper to call attention to its natural limitations, which at the same time account for the observation of only partial or negative results in its application to existing tuberculous disease.

The limitations arise chiefly from the degeneration of tuberculous tissues, and from associated exudative and productive inflammations, and but for these we could more readily dispense with a combination of dietetic, hygienic, and climatic methods which are the more important, the more marked, extensive, and advanced the degenerative and inflammatory processes have become, to which are attributable most of the active manifestations of phthisis.

The specific part of the treatment can be expected to arrest the tuberculous process, to prevent further degenerative changes in tuberculous tissue by favoring its vascularization and cicatrization, or its resolution and absorption; but unable to restore the more advanced changes, it cannot be expected to remove or restore necrotic tissue or the inflammatory products due to associated bacteria or the symptoms upon which they depend.

The more advanced the disease has become the more is the future determined by conditions beyond the control of specifics, and although the latter may have accomplished all that I have indicated as possible, and the organism have become immune to the action of the tubercle bacillus, the disease can, nevertheless, progress by softening, excavation, and suppuration of caseous tissue, and by incidental inflammation and complications which can occur in the course of these changes, and the patient may die from their effect. This being the case, we see not only the great importance of early specific treatment, but also of its combination with general measures, calculated to restore and to maintain the patient's nutrition and general resistance.

Bearing these limitations in mind, we can readily understand not only the frequently observed prompt recoveries of an enduring character following upon specific treatment, but also the partial or negative results as well as the relapses which others and I, myself, have observed.

Considerations of this kind will supply the answer to inquiries received by me frequently concerning the observed continued presence of tubercle bacilli in the sputum of patients who are presumably immunized against their action by showing that immunity, no matter how complete, would be powerless to remove the bacterial bodies from caseous tissue, softening or exfoliating from the walls of cavities, and from other open surfaces, although perfectly capable of protecting the living tissue against their pathogenic effect.

In practice the decision as to the degree of utility of specific medication in a particular case would offer less difficulty to the physician if he could always draw correct inferences from his examination of the histologic changes actually present, and the greater his ability is in this respect the more likely will he be preserved from error. If he believes that with their extent and nature and the symptoms present the patient can reasonably be hoped to have his disease arrested or cured, providing no further for-

mation and degeneration of tubercle would occur, and if the present phase of the disease is not an actively progressing one, and is not attended with acute inflammatory or exhausting complications, under which the nutrition is rapidly failing, and the latter is still fair, the case may be treated with the expectation of benefit and the degree of the latter would depend upon the stage which the tuberculous changes have actually attained and likewise upon the advantages of general care and management available especially for patients who have progressed to an advanced stage.

CONGENITAL OCCLUSION OF THE CHOANÆ.

WITH REPORT OF TWO CASES.*

By JOHN EDMUND MACKENTY, M.D.,

NEW YORK,

ASSISTANT SURGEON, MANHATTAN EYE, EAR, AND THROAT HOSPITAL.

Few malformations have received so little attention as congenital occlusion of the posterior nares. The most recent pathological treatises speak very briefly of this condition. In the text-books of Zuckerkandl, Mackenzie, Moldenhauer, and Moure only summary descriptions are given, while in Bosworth, Brown, Lennox, and Lyons no mention of it is made whatever. References to it are very scattered in medical literature.

The first report of a case was by Emmert in 1853, a double occlusion. The next report of a case came in 1868. Voltolini in 1870 cites a unilateral case. Betts in 1876 relates a double bony occlusion in a newborn child. Solis-Cohen in 1880 reports a case of double occlusion in an infant with violent suffocation. Donaldson in 1880, having occasion to perform many autopsies on cases of asphyxia neonatorum, mentioned this condition as a cause of death, but gave no percentage of its frequency. Haag, in 1889, reviewing all the cases reported prior to that date, cites 53 verified and 15 unverified. Boulay in 1902 reviews 80 cases, and Texier in 1906 brings the number of verified and unverified cases up to 98, two of which he discovered dead of asphyxia in the newborn.

That these 100 cases give more than a fraction of the number of cases in actual occurrence, and that this deformity is the cause of a certain number of deaths from asphyxia neonatorum, and that the condition in infancy passes unrecognized, may, I think, be stated without controversy.

The explanation of this deformity is not easy, without invading the field of hypothesis. As I shall endeavor to point out later, this defect must have its origin at a very early period of fetal life. Opinions differ as to which bone or bones give origin to the occlusion. Kundrat and Schrötter attribute it to the vertical plate of the palate bone; Luschka to the horizontal plate of the same bone. Great thickening of the posterior end of the vomer has been observed, and in one case the deformity undoubtedly had its origin in the body of the sphenoid. True sutures have been observed uniting the occluding bone with the juxtaposed parts.

We know that these occlusions are in the true sense not pathological, since the bone in them shows the histological elements of bone, and they are covered by a true mucosa continuous with the pharyngeal mucosa behind, and with the nasal mucosa in front. They may be unilateral or bilateral, bony or membranous, or partly bony and partly membranous. They vary in thickness from a mere membrane up to 12 mm. Boulay in 65 cases found the occlusion to be: Bony in 51, membranous and bony in 7, membranous in 7.

In the combined bony and membranous type the central portion of the barrier is membranous, while the peripheral portion is composed of converging spicules of bone. The occlusion may lie even with or just anterior to the posterior end of the vomer. In adults, at least, unilateral occlusion is vastly more common than bilateral, and bony occlusion is more common than membranous. Just what the relative percentage at birth may be cannot be said, since a very large number of those with double occlusion must die in infancy.

That syphilis is a factor in the causation of congenital occlusion I am inclined to doubt, though it may cause a post-nasal atresia occurring before or after birth. Rault cites two cases of occlusion due to syphilis. The occlusion in these was membranous and the bony walls were normal.

Schwendt, in 1890, in an exhaustive study, states that in the majority of cases there is no other organic defect.

Arching of the hard palate, deviations and ecchondroses of the septum, atrophy of the occluded side, and hypertrophy of the open side may be present. In double occlusions extensive atrophy of the nasopharynx and pharynx is the rule. The eustachian orifices may show pathological changes, generally atrophy, and otitis media, sclerotic or purulent, is observed in a certain number of cases.

The only attempted explanation of this deformity found in the various published articles attributes it to local hypernutritive changes in embryonic life. As this deformity has a definite anatomical appearance in post-natal life, so it seems to me, it must have a likewise definite embryological cause.

Let us consider briefly the embryology of this subject. The septum is formed from the so-called midfrontal process, which is a prolongation downward and forward from the middle of the base of the skull. It is a thick, more or less shapeless mass of embryonic tissue. On either side and parallel to it, and springing also from the base of the skull, appear the so-called maxillary processes. These, descending, form the outer walls of the nasal fossæ. Thus two fossæ are formed on either side of the midfrontal process or septum. These fossæ and the space below them are at this time continuous with the buccal cavity. Extending from the inner surfaces of the above maxillary process, two new processes extend horizontally toward each other (so-called palatine processes) and fusing form the palate. This occurs about the fourth week. It must be noted that these processes (the midfrontal and maxillary) are thick masses of protoplasm lying in contact with each other, so that the nasal fossæ, at this time, are only potential cavities.

The ventral infolding of the lateral plates of the embryo, when they coalesce and fuse, forms the primitive gut. With the cephalic end of this gut we are here interested, since it enters into the formation of the pharynx and nasopharynx. At this period of fetal life the foregut is shut off from the buccal cavity, and only later becomes continuous with it by a process of absorption.

In these few embryological facts we have at least some basis for the hypothesis that at this time of fetal life may be laid the foundation of the future deformity. We see that the septum and external walls lie in contact, also that the buccal cavity is

*Read before the Section on Laryngology and Rhinology, New York Academy of Medicine, February 27, 1907.

shut off from the parts behind. Undue embryological activity at the points of contact between the midfrontal process or septum and the maxillary processes, or external nasal walls, might easily result in the overproduction of new tissue in the posterior nasal openings, which subsequently, following the nature of its environment, becomes ossified.

Prior to the development of the palatine processes, we note that the nasal fossæ and buccal cavity form but one cavity in front of the closed foregut. May it not be possible that failure of this dividing wall to be absorbed at the proper time leaves this congenital occlusion?

The symptoms in any given case must depend necessarily upon the amount of occlusion present. In double occlusion the symptoms are marked from the beginning of life. The child is born in great asphyxia. The peculiar relation of the tongue and lower jaw to the palate make breathing for it more difficult through the mouth than for the adult, and unless the mouth is opened wide, and the tongue drawn away from the palate, fatal asphyxia may ensue. Nursing is impossible and vomiting the rule. The child is reared on the spoon, is underfed, and shows marked malnutrition in the early months of life. Frequent attacks of suffocation occur. If the child survive the nursing period, it becomes more accustomed to the lack of nasal breathing, and if it does not succumb to some acute pulmonary affection, such as bronchopneumonia, it may reach adolescence.

The majority of cases present themselves for treatment between the tenth and twentieth years. Here, again, the symptoms depend upon the amount of obstruction present, many unilateral cases being discovered by accident.

The adenoid facies may be marked, the voice lacks nasal resonance; smell is always absent on the obstructed side, nor does it as a rule develop after operation. Taste may be diminished, and in one case was absent on the affected side.

The nasal ala of the occluded side is immobile. The nasal mucosa may be unaltered, but generally shows atrophy. The turbinates are as a rule well developed, though in one of my cases were rudimentary on one side. The nose and nasopharynx on the affected side are filled with secretions and crusts, sometimes difficult of removal. Deafness, and consequent stupidity, is a marked feature in many of the bilateral cases. Frontal headache is usually complained of. Snoring and mouth breathing are present in proportion to the degree of obstruction. Anemia and lack of physical development are observed, as in all cases of serious impairment of nasal breathing.

The diagnosis in adults is easy, if a systematic examination be made and a careful history taken. The pharyngeal touch and mirror, in conjunction with the probe in the nasal fossæ, give exact information upon the character and position of the occlusion.

In infants the diagnosis is more difficult, requiring at times considerable ingenuity to demonstrate the condition present. A bent probe in the nasopharynx, and another passed through the nose, should touch each other if the choanæ are open. The obstetrician should keep this condition in mind in asphyxia neonatorum, and in defective nasal breathing in children it should be thought of as a possible cause.

Other conditions producing nasal obstruction (which may be confounded with this type) are: Adenoids (which it may be well to note may coexist), syphilitic rhinitis with atresia, congenital synechia, retropharyngeal tumors (osteomata, myomata, fibromata), high retropharyngeal abscess, intranasal tumors of all kinds, intranasal hypertrophies, foreign bodies in the nose. In syphilitic atresias true bone does not exist. The occlusion is not covered by a normal mucosa, but is made up of scar tissue.

Prognosis as to life, excepting in the newborn with complete occlusion, is good. Suffocation, inanition, and pulmonary infections must prove lethal in many of the double occlusions. The brunt of the affection in the more pronounced cases falls heavily upon the general health, as shown in lack of physical development, malnutrition, sclerotic and suppurative otitis media, and atrophy, which fail entirely to disappear even after nasal breathing has been restored.

Some of the methods of treatment I shall merely mention in order to condemn. Many men in the past seem to have been inordinately fond of the galvanocautery, electrocautery, elastic cannula, elastic hougie, the gouge and mallet, and many other clumsy devices for the relief of this deformity. Some, in order to make more room for these crude procedures, have not hesitated to remove *in toto* the inferior turbinate.

In the newborn it is essential to operate at once if the occlusion be double. An opening is here quite easy of accomplishment, as the obstruction is generally cartilaginous, or, if bony, quite soft. But, on account of the smallness of the choanæ, this opening is equally hard to maintain. A trocar is the instrument generally employed, but I would not hesitate to use a properly constructed dental drill. Mere puncture does not remove anything, and cannot be expected to leave a permanent opening.

In children with unilateral occlusion the urgency for operation is not so great, excepting for the prevention or diminution of the atrophies and of the ear complications which may form sequelæ.

Two conditions must be fulfilled in operating: (1) Remove the obstruction without injury to any important structures in the vicinity; (2) keep the opening patulous.

In children, general anesthesia is necessary. In adults, cocaine anesthesia is sufficient.

The structures which must not be injured are: the inferior turbinates, the removal of which is never justifiable for reasons too evident to require enumeration; the eustachian orifices, which may easily be wounded if care be not taken in using instruments on the outer wall.

Lying on the outer wall, and just anterior to the choanal opening, is the pterygopalatine canal for the transmission of the pterygopalatine vessels and the pharyngeal nerve. Just beside this is the posterior palatine canal, which transmits some of the descending branches from Meckel's ganglion, nerves of sensation to the nose, roof of the mouth, and pharynx and motor nerves to some of the pharyngeal muscles (the levator palati and azygos uvulæ).

From the foregoing we observe that all the important structures in this region lie upon the external nasal wall, and it is on this side, therefore, that care should be exercised.

The dental drill and the punch forceps of various forms, in my opinion, are all the instruments required in the performance of this operation. When possible the finger should be kept in the nasopharynx as a guide while the drill and forceps are being used.

As much as possible of the opening should be made upon the floor, inner wall, and root of the choanæ. When a sufficient enlargement cannot be made, I would strongly advise removal of the pos-

terior end of the vomer. This places the choanal openings more anterior and in a less contracted part of the nasal cavity.

Any procedure, such as packing with gauze or the use of elastic wedges, I believe to be entirely useless, and only a source of irritation. The principle is to make the choanal openings so large that they cannot close by granulation and cicatrization. This can always be done if need be by the removal of the posterior end of the vomer.

Case I. Double Complete Occlusion of the Choanæ.—J. R., aged 17, male, student, of Irish parentage, came under observation December 15, 1902. Complained of inability to breathe through the nose, and a discharging right ear with gradually increasing deafness in both ears. The mother stated that the patient was brought through his nursing period only by the greatest watchfulness. He could not take the breast or bottle, was fed with a spoon, had frequent attacks of asphyxia at night, and at the end of the first year was badly nourished and small. The boy was tall, slim, and anemic, with a poorly developed chest. The face was flat, external nose well developed, mouth receding, labionasal folds deep, due to sinking of antrum walls, malar bones prominent, upper jaw narrow in front, lower jaw well developed, head flat from before backwards and wide laterally, mastoids prominent, ears prominent. No marked asymmetry in the head or body. Nasal fossæ both filled with mucus and scabs. Septum slightly deviated to the right. Over the deviation, on right, great thickening extending from the floor to the middle turbinate region and from the anterior third of the triangular cartilage to within 12 mm. of the occluded choana. This mass obscured all view of the turbinates on that side. They were subsequently found to be rudimentary. The posterior opening was closed by a dense bony wall, which we later found to be 6 mm. in thickness. On the left side the nasal fossa was ample, the turbinates well developed. The posterior opening was obstructed by a bony rim with a membrane placed eccentrically in its upper and outer aspect. The nasopharynx was filled with dried secretions. On removing these the mucous membrane was found atrophied. The eustachian eminences were abnormally prominent and the mouths of the tubes were very pale and patulous. The nasopharynx was abnormally wide and deep, but much shortened in its perpendicular direction. Two indentations showed the position of the closed choanæ. A continuous smooth, mucous membrane covered these, showing no evidence of a former inflammatory process. The palate was arched and the front teeth crowded. The pharynx was atrophic. The larynx was large and well formed, the vocal cords dull, the arytenoids puffy and dark red.

There was considerable loss of hearing for the spoken and whispered voice. A watch could be heard at 30 cm. in the left and 5 cm. in the right ear. The right drum was destroyed, excepting a rim at the upper anterior portion. The tympanic wall was pale and glistening. A mucupurulent discharge, at times profuse, was constantly present. The left drum was pale and contracted and congested in its upper anterior portion. It responded to pneumatic vibration quite well. The right eustachian tube was very patulous. The left had a stricture 2½ cm. from its pharyngeal end.

Operation under cocaine. The occluding membrane on the left was incised and the bone removed with punch forceps and burr on a dental drill, going deep into the floor and inner wall, but avoiding the outer wall. At a second operation the bony exostosis on the right was removed, saving the mucous membrane. At a third sitting the right obstruction was drilled through and the opening enlarged, as on the other side. No packing or dilator was used to maintain the openings patulous. Enough bone was removed to insure this.

Result, four years later: Nasal breathing perfect. Nasal atrophy still present. Nasopharyngeal atrophy much improved. Hearing 60 cm. left ear, right ear unimproved. The patient gained 30 pounds in the year following operation.

Case II.—Unilateral Bony Occlusion of the Right Choana. A. D., aged 15, female, French; came under observation September, 1905. In early childhood no symptoms were observed by the mother. From the seventh to the twelfth year mouth breathing and snoring were complained of, and in her twelfth year an adenoid was removed, with considerable relief of the symptoms. Patient was small in stature, fairly well nourished, but anemic. About one year prior to the consultation she observed that breathing was impossible through the right side of the nose; the left was good. There was some asymmetry of face. The right side was smaller than the left. The right eye was smaller and on a slightly lower plane than the left and the malar eminence less pronounced. There was no other physical asymmetry. The external nose was well developed. Septum straight in its anterior two-thirds. Posterior one-third deviated to the right. Right fossa full of secretions and scabs. On removing these the turbinates showed somewhat atrophic. So narrow was the posterior third of the fossa that the occluding wall could not be seen. The left fossa was normal. The nasopharynx showed the vomer deviated to the right, and a slight dimpling marked the position of the right choana. Hearing normal. Taste normal. Smell on good side normal.

Operation under cocaine. Opening was drilled through a very dense bony wall 3 mm. thick. In enlarging this opening the posterior part of the vomer was drilled away. Even then the result was not satisfactory, and at a subsequent operation about 3 cm. of the posterior end of the vomer was resected.

Result, present time, perfect nasal breathing.

There are two opinions relative to the causation of arched palate. The one holds that arched palate is an accompanying part of a peculiar type of face called leptoprosopia, which means the long, narrow face. The other holds that it is due to defective nasal breathing at an age when the bones of the face are more or less plastic.

Measurements Case I.

Superior facial index	6.8	Height	=48.5
	14	Breadth	
Nasal index	2.5	Height	=50.0
	5	Breadth	
Palate index	2.7	Height	=62.7
	4.3	Breadth	

Measurements Case II.

Superficial facial index	7.5	Height	=57.7
	13	Breadth	
Nasal index	2.1	Height	=41.9
	5.2	Breadth	
Palate index	2.5	Height	=59.5
	4.2	Breadth	

The measurements taken in these two cases (in both of which the faces belong to the broad type of head) would go to prove that the arched palate is due to nasal obstruction, since all the measurements are fairly normal except those of the palate. Here we have, instead of a normal of 45 or 48, in one case 62.7 and the other 59.5.

THE MISUSE OF THE VOICE AND ITS CURE.

By N. J. POOCK VAN BAGGEN,

THE HAGUE, HOLLAND

When in America last summer I was frequently asked to give a detailed explanation of the treatment which we use for throat diseases, caused by the inexperience of using and misuse of the voice. I am anxious to explain as clearly and as completely as possible the treatment by which so many speakers and singers have been cured and enabled to continue in the profession of their art. But I encounter a great difficulty; I can explain which muscles are used for speaking and singing, how we must best use them, and how the different groups of muscles must cooperate together to produce a normal and easy way of speaking and singing; I can also explain where the sound or vibrating air must strike the hard palate in the mouth to make the voice carry far, but I cannot give a definition of the part of the work which is done by the ear. The teacher relies for a great part, and even often entirely, on the ear to distinguish a faulty voice production from a good one, while the pupil must be practised to distinguish through the ear a wrong tone from a good one, which latter he must try to imitate from his teacher. The great part which the ear takes in the teaching of the method seems also to me the reason why there does not yet exist a good and complete manual of the method, which has now been taught for about twenty years in Holland.

I have been asked in which cases of throat diseases the treatment can be used with success. In my article entitled "Throat Diseases Caused by the Misuse of the Voice," published in the Medical Record of January 5, 1907, I gave a description of the throat disease caused directly by the misuse of the voice and wherein this misuse consists. In this special case the treatment has always been employed with good results. Sometimes in chronic cases the recovery comes only after a long time, but it never fails to come. There are no relapses.

When enlarged tonsils, adenoids, nasal polypi, deformations of the tongue, or tumors in the larynx are the cause of the aphonia or of the speech impediment, the treatment may be necessary for the muscles weakened by the disease, or when, which is often the case, the patient fails for lack of energy to break himself of an impediment to which he has become accustomed and which was caused by the local defect.

In paralysis of the vocal chords resulting from diphtheria the treatment combined with electric massage is applied with success.

Not only do patients make use of the treatment nowadays, but many of those whose profession demands constant use of the voice go through it to learn how to use their voice properly and how to strengthen it so as to resist the most fatiguing labor.

As speech and singing are effected by the combined action of the breathing, articulating, and vocal muscles, the action of each of those groups of muscles will be considered. The breathing being the motor element, and therefore the principal element of speech, the breath and breath-practice must be considered in the first place. The questions of articulation, of the use of the vocal muscles, and of resonance will be treated of later.

Breathing.—As the breath is the chief element for producing voice and speech, the patient has to learn in the first place the right way of breathing, and how he may make the best use of the breath in the production of the voice; in short, he must learn "breath practice." The right way of breathing means inspiring and expiring a large volume of air in a way which does not hinder the larynx in its movements and does not occasion a pressure on the arterial and venous vessels and the tissues of the throat.

We make the best use of the breath in voice production only when we know how to control it properly and how to direct it consciously.

We breathe by enlarging and contracting the chest or thorax. We can do this in different ways; either we enlarge the chest by raising the upper part of it, or we extend it sideways, or we elongate it by contraction of the diaphragm. In the first case we speak of clavicular breathing, in the second of costal breathing, in the third of diaphragmatic or abdominal breathing. Those three forms of breathing are of course not totally independent one of the other: the contraction of the diaphragm cannot take place without occasioning a lateral extension of the ribs, while the full clavicular breathing will also be united with some lateral inflation of the chest.

We will consider those three forms of breathing and see which form we must reject and which offers us the most advantages to meet our purpose.

In the case of clavicular breathing we enlarge for inspiration the upper part of the chest. To execute this movement we must raise the collar bones (and with them the arms), the shoulder blades, and the upper ribs which are attached behind to the spine and in front to the sternum, all hard and unyielding parts. It is clear that this cannot be done without a great effort, the result of which is that the upper part of the chest walls is pressed against the root of the neck and its large vessels, forming an obstacle to the free movement of the larynx and causing congestion of its vessels, while the amount of breath we get through this way of breathing can be but small, because the apices of the lungs, that is, the narrowest part of them, only will be able to swell to their full extent and be inflated with air.

By this mode of breathing it is also impossible properly to control the exhalation. After having raised with great effort those hard and unyielding parts of the chest, a much greater effort, which a singer or speaker is hardly capable of, must be car-

ried out to keep the thorax a moment in this attitude, and then contract it slowly, as is required for a properly managed exhalation. We usually observe in this case that, for want of strength to execute this forced movement, the singer or speaker gives way and loses all control over his breath. It is unnecessary to say that, by this way of expelling the air, the voice, for want of proper support, is unsteady and fails to carry far. Thus in every respect we must condemn clavicular breathing, and even carefully avoid it, as it certainly is one of the causes of the throat disease already described.

By lateral extension of the thorax, or costal breathing, the clavicles remaining at rest, there is no pressure on the root of the neck nor on its great vessels, and the lungs are inflated where they are largest and can contain a large amount of air. So far this way of breathing thus is better than the first named; however, when comparing costal breathing with diaphragmatic breathing, we must decide in favor of the latter. By experiments made with the spirometer on a great number of individuals, it has been proved that the amount of air, we can inhale, is less by costal breathing than by diaphragmatic breathing.

In regard to control over the breath when exhaling, costal breathing is also inferior to diaphragmatic breathing. To extend the walls of the chest sideways for inhaling we lift up the lower ribs by contraction of the outer-intercostal muscles. In exhalation the ribs are lowered by relaxation of the outer-intercostal muscles and contraction of the inner-intercostal muscles. Only those two groups of muscles work during the process of costal respiration. During diaphragmatic breathing, in expiration the action of the outer-intercostal muscles resists that of the abdominal muscles and hinders the contraction of the diaphragm. It is this resistance, which is wanting in costal breathing, that enables us to exercise a better control over the breath. In the case also in which all the labor must be performed by two groups of muscles, fatigue will sooner appear than when the same amount of labor is divided over more groups of muscles. So we come to the conclusion that costal breathing, though satisfactory in many respects, does not equal diaphragmatic breathing. In some cases of abdominal diseases it may be necessary to avoid abdominal respiration. In those cases costal breathing must be taught, and when well exercised good results can be obtained.

The lower part of the chest is formed by the floating ribs and, at the base, by the diaphragm, all soft and easily yielding parts, which can be contracted and relaxed for a great length of time without causing much fatigue. The lungs being largest at their base, we obtain the greatest possible amount of air by enabling these organs to expand downwards.

In inhalation, by diaphragmatic breathing, the abdomen is pushed forward, the center of the vaulted midriff flattens, and its outer edge, which is attached to the lower ribs, slightly rises, causing a lateral and upward extension of those ribs. In exhalation, when speaking or singing, the abdomen is pressed against the flattened midriff by the contraction of the foremost section of the outer-oblique muscles, and the diaphragm relaxes. This relaxation, however, is opposed to by the action of the outer-intercostal muscles, which try to keep the ribs in their position of extension. The opposition between those different groups of muscles stems exhalation more or less, and gives us the opportunity of exercising a good control over expiration.

Thus in all respects the diaphragmatic breathing is the best of the three forms, and is that which we generally teach for speaking and singing to our pupils and patients. I will try to explain briefly how we proceed in doing this.

As we have seen before, in diaphragmatic breathing the abdomen is pushed forward in inspiration, and in expiration, during speaking and singing, the abdomen is pressed against the diaphragm. Thus the first exercise will consist in: pushing forward the abdomen and contracting it. To make it easier, and to prevent false movements, we exclude the idea of breathing by this first exercise, and see to it only that in contraction of the abdomen the foremost section of the *musculi obliqui externi* is used, and not, as sometimes is the case, the *musculi transversi*.

For the second exercise the same movements are made, but combined with inhaling and exhaling through the nostrils.

The first day those exercises must be made for only a few minutes three or four times a day. Every day, however, they may be continued a little longer and done oftener, until the pupil gets accustomed to this mode of breath practice and adopts it as his natural way of breathing. In the beginning the pupil must lie flat on the back when exercising; he may afterwards try to exercise in every position—sitting, standing, and even walking.

No tight garments must incommode the thorax or the abdomen in their movements.

When diaphragmatic breathing offers no more difficulties to the pupil, the breathing as used for speaking and singing must be learned.

When we breathe solely for the maintenance of life we inhale, exhale, and then rest a moment before we inhale again. The inhalation is an active movement, the exhalation and the rest or pause are passive. When using the breath for voice production, in speaking and singing, we inspire, retain the breath a moment, and then expel the air gradually. This retaining and this expelling of the breath are active movements just like inspiration. Everyone of these movements must be equally developed in strength.

The third exercise is as follows:

1. Inhale slowly through the mouth, the underlip leaning against the upper teeth, as when saying *f*, count five mentally.

2. Hold the breath, count three (this holding of the breath must be governed entirely by the abdominal and costal muscles, and not by the shutting of the glottis, which must be open as well as the mouth).

3. Exhale pronouncing a prolonged *s* finishing in *t*, count ten. Thus inspiration, 5, on *f*: pause, 3; expiration, 10, *s-t*.

The *f* in inhaling and the *s* in exhaling are used as tell-tales by which we assure ourselves that the inhalation and exhalation are done evenly, without shaking or interruptions.

Gradually the time in which the three actions are executed is increased, but never so far that, after inspiration, the lungs are overdistended with air, and the expiration is unsteady because of the breath being held too long.

As the breathing power differs with each individual, and at every age, a fixed limit cannot be adopted for this third exercise. The experienced teacher has to decide here how far the pupil may increase it. If the chest expansion remains insufficient after having exercised some ten days, or if it appears that some of the groups of muscles are particularly weak, special exercises (which I cannot mention here) must be prescribed and continued till a normal respiratory power is attained. The aim of

the next exercise is to teach the pupil to inhale quickly, hold his breath a moment, and exhale as slowly as possible, as must be done when speaking or singing.

1. Full inspiration through the nostrils.
2. Pause, 1.
3. Expiration, 40 or more on *s-t*.

These latter two exercises are exclusively meant to teach the pupil how to control the breath. The next thing to be done is to teach him how to direct the breath consciously and how to make the breathing muscles cooperate harmoniously with the articulation and vocal muscles.

The most serious and most general fault of speakers is that the breath or vibrating air strikes the soft palate instead of the front wall of the mouth, formed by the upper teeth, the alveolus, and the hard palate, which constitute our natural sounding board. A faulty articulation will not do the harm which the breath directed in this way does, and every teacher must be careful to correct this fault thoroughly.

The first exercise to learn how to direct the breath is as follows: Inhale through the nostrils, exhale through the mouth; then inhale through the mouth and exhale through the nostrils and make the pupil notice the different directions in which the breath is led.

To make the vibrating air or sound strike the front wall of the mouth we use the following exercise: Take a full inspiration, counting 3 mentally, hold the breath counting 2, say *ha* contracting suddenly and with energy the abdominal muscles (the *musculi obliqui externi*). By this energetic exhalation the air is projected with force against the front wall of the mouth, where the tone can resound clearly. Repeat the same exercise, but instead of *ha* say *lah*! When pronouncing the *l* we lean the tip of the tongue against the upper alveolus; exactly at that same place the sound must strike our sounding-board while we are speaking. The letter *l* is used as a guide to the breath. It is here that the pupil must try to imitate the examples of his teacher, who can judge only by hearing if the tone is well placed. If it is well placed it will be clear and resound through the room.

When the *lah* is well done, try the same exercise, but instead of *lah* say *lah, leh, lai, lee*. Pronounce each syllable separately, taking before each a full inspiration and expulsing the air energetically by the contraction of the abdominal muscles. Immediately afterwards, this same *lah, leh, lai, lee* must be pronounced, but now binding the syllables and in one exhalation contracting slowly the abdomen. While doing this the pupil must try to imitate the clear sounds, which he has just produced by the sudden energetic expulsion of the breath. The same exercises must be made with the other series of sounds (to be considered when treating of articulation) and bye-and-bye in combination with all the voiced consonants, then also with the breath consonants.

These exercises, of which the purpose is in the first place to learn how to direct the sound forward, are at the same time an excellent help to reestablish the harmonious cooperation of the different groups of muscles, which is nearly always disturbed by the catarrh. We have seen, in the former article, that paresis of the vocal chords is one of the symptoms of the throat disease in question, and the injudiciously used breath passes the weakened vocal cords without being able to make them vibrate. With a well-controlled, energetic exhalation, supported by an exact articulation of one of the voiced consonants, the vocal cords are stimulated and will produce a sound perhaps not altogether clear in the beginning, but which will improve daily, while at the same time the closure of the vocal cords will be improved.

When the above mentioned exercises have been practised with all the sounds and consonants, the pupil must try to pronounce short words in the same way, at first each word separately, then again binding three or four words together. Little phrases may be practised then, which soon can be followed by the narration of a short story and some specially chosen easy reading. More difficult materials can be used as soon as the pupil has become accustomed to his new mode of speaking and can watch over it with less exertion.

The pupil must be careful that, when pronouncing the words combined in one breath, the outer-oblique abdominal muscles are contracted slowly, but distinctly and consciously. (The teacher will explain to the pupil how he can control himself by placing the hand laterally on the abdomen.) This will teach him to govern his speaking by the breath which is required for a normal speech.

In the beginning the exercises must be carried out but a few minutes, three or four times a day. The teacher has to decide when and how long they can be prolonged; this depends on the condition of the throat and on the effect produced by the exercises on the voice.

At the beginning of the treatment, the patient must not speak at all; bye-and-bye he may be allowed to speak a little, but only using the new way of breathing (and also of articulating). As this will be difficult and fatiguing for him at first he will easily avoid speaking much.

As the intention of this article is to give a general notion of the treatment, I have mentioned only the principal exercises used. Of course there are a great number of other exercises which have in view the normal use of the breath as the motor power for speech and singing.

PLAATS, 10A.

IMPACTION OF FECES.*

By LEWIS H. ADLER, JR., M.D.,

PHILADELPHIA.

PROFESSOR OF DISEASES OF THE RECTUM, PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE; PROSECTOR TO THE PROFESSOR OF ANATOMY, MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA, CONSULTING SURGEON, CHARITY HOSPITAL

THIS subject has not been presented before the Society for some time; therefore, as I have had recently under observation several such cases, the topic seems worthy of consideration in order to invite discussion and obtain the present views of the Fellows.

The result of obstipation, or an attack of constipation, may be an accumulation of clayey feces, formed in the cecum or in any part of the colon; but the term impaction is generally employed when such accumulation occurs in the pouch or ampulla of the rectum or in the sigmoid flexure, and will be so considered in this article.

The ampulla of the rectum or the sigmoid is the most favored site for such a collection of feces, and the deposit may attain very large proportions, being more or less globular in form.

As pointed out by Allingham,[1] there is a marked difference between an ordinary persistent constipation and the disease under consideration, for an

*Read before the American Proctological Society at the ninth annual meeting, held at Atlantic City, N. J., June 3 and 4, 1907.

impaction may follow from a single attack of constipation, whereas obstinate constipation may never, or only after a long period, cause an impaction. Furthermore, the symptoms of the two conditions are very different; impaction being generally marked by a diarrhea, whereas in chronic constipation the prominent symptom is constipation.

The impaction may be due to several causes, but is usually a symptom either of intestinal atony in old people or of some paralytic affection, such as locomotor ataxia, etc. It may arise from a catarrhal condition of the bowel or from undue distention of the coats of the bowel, as from fermentative changes in the contents of the intestinal track, etc. It not unfrequently occurs as a result of the prolonged pressure of the fetus and is most apt to follow confinement.

Foreign bodies in the intestinal canal, such as seeds, fruit-stones, enteroliths, and worms, may likewise occasion this malady. Several cases are recorded by T. B. Curling[2] in which a plum-stone has been found in the center of the fecal mass, forming a sort of nucleus.

The quantity and quality of food taken is sometimes an etiological factor in impaction. I have seen this occur several times following an attack of typhoid fever, due to the prolonged use of a milk diet.

Harrison Cripps[3] states that rectal concretions were a marked feature during the Irish famine of 1846 and calls attention to an interesting paper published at the time by Dr. Popham,[4] who was one of the physicians of the Cork North Infirmary. During the famine many cases of intestinal obstruction, the result of enormous concretions, were admitted into the infirmary. After the obstruction was removed it was found to consist of decayed portions of potato mixed with the undigested peel, which had been consumed by the half-famished people.

Fissure in ano and any congenital or acquired narrowing of the lumen of the anus or the rectum as well as an abnormal condition of the rectal valves may occasion the disease under consideration.

The malady is generally one to which old age is heir, and especially does it seem to have a predilection for the female sex. I have personally never seen the condition occur in the male, but that it does affect all ages and sexes is amply shown by the recorded literature.

Dr. Jos. M. Mathews[5] states that he has met with this condition in persons of middle life, in the aged, and in the young, and attributes most of the trouble to obstinate constipation, due to the modern rush and the consequent neglect of all the essential rules of health. Continuing, this author states that he has been called repeatedly to attend young girls who have never been instructed in the ordinary health rules, and who scarcely know that they possess a rectum, and are not aware of the fact that their bowels should be evacuated at stated intervals. Personally, I am convinced that women are most careless in this respect and seem to justify the definition of a prominent gynecologist, now deceased, who defined them as "constipated bipeds."

The symptoms to which impacted feces give rise are generally sufficiently well marked to enable the wideawake practitioner to reach a correct diagnosis. The only characteristic symptom present, however, is diarrhea, which is of the most annoying and persistent kind, resembling markedly the condition of the bladder obstructed with an enlarged prostate, in which the so-called incontinence is not a sign that the viscus cannot hold any quantity of fluid, but on the contrary is due to retention of urine and an inability to empty it. In some cases the movements of the bowels have a peculiarly offensive odor. The stools are usually liquid, but may contain solid particles; sometimes blood and mucus may be passed either alone or with a fecal movement. This condition of the bowels finally leads to a catarrhal dysentery produced by the irritation of the arrested mass.

Extensive ulceration may supervene as a consequence. Sir Chas. B. Ball[6] cites a very remarkable case of this character seen by him in consultation with Dr. Wright of Dalkey, in 1884. The patient was a widow, aged sixty-five. A rectal examination revealed the fact that the entire lower bowel was blocked with feces. Prior to the examination the cutaneous surface of the right buttock, which had been greatly inflamed, gave way and permitted the escape of a considerable quantity of feces. By carefully breaking up the fecal mass and the administration of copious enemas, Dr. Wright succeeded in evacuating what the nurse described as a "bucketful" of feces. When Mr. Ball saw the patient the wall of the rectum had sloughed upon the right side of the bowel, about one and a half inches from the anus, leaving an opening as large as a half-crown piece. There existed a considerable quantity of feces in the areolar space external to the rectum, and pressure made with the finger externally caused the extrusion of lumps of hard feces as big as walnuts through the large fistulous opening in the right buttock. Eventually, the patient made a good recovery without a stricture following or any other inconvenience.

Associated with the symptoms already mentioned, impaction may be and often is accompanied by tenesmus, colicky pain, flatulence, distention, and signs of collapse, especially after straining efforts at evacuation.

Hypochondriacal symptoms, more or less pronounced, are often present, especially when auto-intoxication exists, as shown by a furred tongue, bad breath, etc. Dr. Jas. P. Tuttler[7] refers to two cases of mental derangement occurring in his experience due to the retention of fecal material in the intestine; and also cites a case which he had seen of epileptoid convulsions apparently due to the arrest of a mass of plum-stones in the sigmoid flexure of a child.

In addition to these symptoms patients sometimes suffer from swelling of the lower limbs and feet due to pressure on the pelvic and abdominal veins, varicose veins of the limbs, varicocele, shooting pains in the lower extremities, groins, and loins caused by pressure of the impacted mass upon the sacral plexus of nerves, etc.

On examination there is apt to be dulness over the iliac fossa and more or less prominence, and a tumor may even be felt if the accumulation extends from the rectum into the sigmoid or is situated within that flexure. On passing the finger into the rectum a solid mass is felt, sometimes apparently fixed, but more often movable, and frequently associated with the presence of fluids, the product of the catarrhal condition induced by the presence of the fecal mass. Sometimes the impaction may be partially covered by mucous membrane which it has pushed down in front of it, as mentioned by Dr. S. G. Gant,[8] when it may be mistaken for malignant disease.

The symptoms of fecal impaction alone are often in themselves sufficient to lead to a mistaken diagnosis of cancer, and more than once I have been led to infer from the description given by the medical attendant in advance of my seeing the patient that a case of carcinoma was being referred. When the mass is not within reach of the finger, instru-

mental examination may be required, but considerable care must be exercised in the introduction and use of instruments for fear of rupturing the bowel, which in its inflamed state is more susceptible to injury than when in a normal condition.

The treatment of impaction consists primarily in the removal of the mass, and secondarily in the relief of the inflammation of the mucous membrane occasioned by the irritating presence of the fecal matter, as well as the removal of all causes which contribute to the constipated habit, which is undoubtedly the prime factor in producing an impaction; such are improper diet, irregularity of attending to the calls of nature, and often an utter lack of outdoor exercise.

The best manner of breaking up the fecal mass is to put the patient under an anesthetic and then forcibly to divulse the sphincters, after which the mass may be disintegrated by means of the finger, a lithotomy scoop, or an old-fashioned iron spoon. In women considerable assistance may be rendered by passing a couple of fingers into the vagina and by this means steadying the mass so that it may be the more readily broken. In some instances I have been able to break up an impaction without resorting to anesthesia, simply by using the finger and sometimes by the additional use of a bivalve speculum and a rectal scoop or spoon.

Previous to resorting to instrumental aid in the removal of the impaction, the fecal mass may be softened and its passage facilitated by the use of enemas. Especially is this so in cases in which the sigmoid is the part affected, in which situation material assistance cannot be gained by the employment of instruments. For the purpose of administering the injections a douche bag holding several quarts is to be preferred. The injection substance should be composed of soap and water, to which I have found the addition of glycerin of considerable benefit, a dessertspoonful to the quart. When the impaction is in the sigmoid the injection should be given through a Wales bougie, preferably the one modified by Dr. Dwight H. Murray of Syracuse, N. Y., which is stiffer than the ordinary article sold, which latter is frequently useless for the purposes intended, as it readily doubles on itself, and a high injection is impossible by its use. When this method is employed the patient should be placed in the knee-chest posture.

Tuttle[7] advises for use as an injection, in ordinary cases of impaction of the rectum as well as in those occurring in the sigmoid, the administration of an enema of about half a pint of warm water containing two drams of inspissated ox-gall and one dram of glycerin; this he directs should be retained as long as possible and repeated four times within twenty-four hours. When this method is employed he has frequently found that the fecal mass has softened so as to enable the patient to pass it without material assistance.

Tuttle[9] has found that impaction in the sigmoid may be dislodged by inserting gently as far as possible the pneumatic proctoscope, twenty-four hours after having injected the glycerin and ox-gall mixture, and then distending the flexure with air. By this procedure he has succeeded in relieving three obstinate cases of impaction, in one of which it was necessary to dilate the sphincters before the mass was passed.

In those cases in which a stricture of the bowel is the cause of an impaction any violent efforts to remove the fecal matter should be carefully avoided, as the gut may be easily ruptured under such circumstances. In this condition, when any doubt exists as to the wisdom of resorting to other expedients, an inguinal colostomy should be performed.

A word of caution should be given here as to the danger surrounding the unguarded use of drastic purgative drugs in cases of impaction. By their employment peristalsis is increased and the fecal mass softened, but the bowel in its inflamed and distended condition may be thereby the more easily ruptured, and if, in addition, a stricture is present, the caliber of the gut may be entirely occluded by forcing into it the hard fecal mass with the attendant symptoms and consequences of total obstruction of the intestines. So much for the treatment of the actual impaction.

In conclusion, a few words as to the attention required for the relief of the after-effects of the impaction itself, and likewise a word as to the avoidance of those factors which directly cause its formation.

Regarding the relief of the inflammation of the bowel due to the irritating presence of the impacted mass, I know of no better treatment than the use of enemas of flaxseed solution made in the same way as is done in the preparation of flaxseed tea. Sometimes I have this medicated with a teaspoonful of compound tincture of benzoin to each pint of water, in order to obtain the additional astringent and soothing qualities possessed by this remedy. These injections should be used once daily for several days. Three to five grains of ichthyol, in pill or capsule, taken by the mouth, every three hours, and continued for a week or ten days, in my opinion, is beneficial.

After the removal of the impaction a ten-grain pill of blue mass should be ordered to be taken at bedtime and followed by a saline the following morning. Remedies should be prescribed to stimulate the muscular activity of the bowel, such as contain physostigma being especially desirable. Glycerin suppositories are useful in regulating the habit of a fixed hour for the bowel movements. Used every day for a week at a set time and then every other day for another week, they have been found most efficient. Exercise in the open air and proper diet are both large factors in the prevention of the recurrence of impaction, and to these conditions careful attention should be given by the medical attendant.

The Scientific Aspects of Cannibalism.—At the recent Congress on Alimentary Hygiene, held in Paris, vegetarianism was opposed by several physiologists, the principle being laid down that the digestion of meat is most easy when the meat eaten is of the same species as the individual eating it. The further the two species, the eating and the eaten, are apart one from the other the more different they are chemically, and therefore the greater the labor required for assimilation. One speaker blandly observed that the principle led to a justification of cannibalism, at least chemically.

INSTRUCTIONS TO THOSE HAVING SYPHILIS.

By VICTOR C. PEDERSEN, A.M., M.D.,

NEW YORK.

GENITOURINARY SURGEON TO THE OUTPATIENT DEPARTMENT OF THE NEW YORK HOSPITAL AND OF THE HOUSE OF RELIEF, NEW YORK

Prof. Alfred Fournier in his valuable work, "Prophylaxis of Syphilis," in speaking of the defects of hospital treatment of syphilis in Paris states that at venereal clinics "printed instructions should be given to each patient," and gives a suggestive form of such circular of instruction. The following circular is not based on Prof. Fournier's and was indeed written three years before his was noted. There is no question in the writer's mind but that such circulars of instruction are of great value because they give to each patient in unmistakable terms the well recognized facts of the disease, which as its victim and its possible source to others he should indubitably know. It also saves a great deal of time to and many omissions by the busy physician. Any statements of such a circular which are not at first reading clear to the patient may readily be made so at a subsequeunt visit, upon his request. Only three of the New York venereal dispensaries issue such printed instruction to their patients.

Into the writer's hands was committed the duty of preparing the circular in use at the New York Hospital and no effort was spared to make it as complete as possible. Its value to the patients has been incalculable; its convenience to the staff of the highest. In publishing and discussing it it is hoped that the heads of other dispensaries in the United States will be induced to follow the same plan of informing the public as to what they should know about this and other venereal diseases, beyond the range of doubt, mistakes, or omissions.

The crusade against tuberculosis in the form of lectures and pamphlets issued by various societies, schools, labor, and charity organizations will shortly bring a rich return in a decrease in the disease. Our duty as physicians is not only to alleviate and cure any disease in the victim, but also to prevent its spread to others. Preventive medicine is the watchword of the age, and the writer thinks that no physician who is a genitourinary and venereal specialist does his full duty to the community or the patient unless he gives such instructions in a most painstaking and conscientious manner.

Such a circular of instruction to those having syphilis should cover four points: (1) A paragraph stating the nature of the disease. (2) Several paragraphs dealing with definite elements in the general management of the disease to prevent its ravages in the patient and its spread to others. (3) Definite instructions as to particular forms of treatment, especially that by inunction. (4) A few words as to general prognosis.

First. As to the few words bearing upon the importance of the disease none can be better than those of Prof. Fournier just referred to, which are quoted in full:

"(1) Syphilis is a disease which is curable, but is only cured by a long course of treatment lasting for several years, even when there is no external sign of the disease.

"(2) It is extremely contagious, especially by the sores and erosions, however small they may be, which generally occur on the genital organs and in the mouth, but which may be produced on any part of the body. A patient with syphilis must, therefore, abstain from any sexual intercouruse when he has the slightest lesion on the genital organs. He must also abstain from kissing when he has sores on the lips or tongue; for a kiss, even on the healthy skin, may be contagious. Contagion may also be transmitted through the medium of any object which has been in contact with the morbid secretions of the disease—glasses, spoons, forks, bottles, pipes, cigars, cigarettes, linen, towels, clothing, etc.

"(3) Syphilis is hereditarily transmitted to children (who generally die) when it has not been sufficiently treated. A syphilitic subject should not marry till after at least three or four years' methodical treatment and then only by permission of a doctor.

"(4) A child born of a syphilitic father or mother should never be confided to a wet-nurse, because it may transmit syphilis to this nurse.

"(5) When a syphilitic subject is affected with any other illness he should always inform his doctor of his former syphilis, for this declaration may be useful for the direction of treatment and the cure of the complaint."

To which might be added the following from the writer's pen, and embodied in the circular now in use at the New York Hospital: "Syphilis is a treacherous and dangerous disease of the entire system and requires for perfect cure at least two, better still, three years of faithful treatment, because it is 'in the blood.' Healing the chancre and taking medicine for a few weeks or months will not cure your blood of the syphilitic poison. It is, therefore, necessary that you follow the doctor's orders most carefully. If you do not you are in danger of having the disease appear in the future in some important part of the body, like the brain, spinal cord, bones, arteries, or other organs, as the liver. If you do not follow directions it is also possible that your wife and children will acquire the disease from you."

The second detail concerning special directions is covered in the writer's circular by the following points which one might discuss in turn: The patient should be told these directions are of particular importance during the first twelve or eighteen months, and whenever thereafter through neglect the symptoms may break out again. Liquors containing alcohol in any form must not be taken, because alcohol is a poison when it is taken in the manner in which most people use it, which poison being added to the poison of the syphilis makes the syphilis much less likely of perfect cure. The patient should be warned not to smoke or chew tobacco because the irritation of the tobacco fumes and juice increases the severity and duration of the sores of syphilis in the mouth and throat and may indeed cause a fresh outbreak of such sores long after they have previously disappeared. Sour, acid, peppery, and spicy foods and pickles should be avoided for the same reason, namely: because they irritate the lips, gums, tongue, and throat and thereby bring about the same results as the tobacco smoke or juice.

The patient should be taught that cleanliness of the teeth and mouth decreases the severity and the duration of the mouth symptoms of syphilis. For this reason the teeth should be brushed and the mouth should be washed every night and every morning. Warning should be given that no other person should be allowed to use the same tooth brush or mug, and that since decayed teeth by their sharp edges and corners and by the infectious ma-

terial their cavities contain may in themselves set up and prolong the mouth signs of syphilis, a dentist should be consulted to treat the teeth just as soon as the diagnosis of syphilis is made. Emphatic and unmistakable directions should be given to tell the dentist that the patient has syphilis, so that he may take precaution against catching the disease himself and against giving it to other persons by using in their mouths instruments infected by the patient's mouth.

In order to prevent giving the disease to the family, the friends, and associates of the patient he should be carefully told to observe the following rules strictly: He should always sleep alone, or, if this is impossible, he should always sleep on the same side of the bed, using the same pillow, so that the discharge from the mouth and other parts of the body during the first few months or year of the disease will not come into contact with a bedfellow. Toilet articles belonging to the patient should also be kept individually for his use. This rule applies in particular to towels, brushes, combs, shaving brushes, razors, soaps, etc.

It is in the majority of cases better probably to state, at least in the severer cases of syphilis, that the patient should not go to a barber to be shaved, because the blood of such an individual may infect a razor and the razor in turn transmit the disease to an innocent person.

The patient should be made to understand that the mucous patches of the mouth are particularly dangerous to other people, and, therefore, he should be most careful to preserve for his own use any article which has been in his mouth, such as tooth brushes, toothpicks, pencils, pipes, cigars, cigarettes, forks, spoons, cups, etc. The habit of kissing is in itself dangerous enough. It is particularly so during the active period, namely, the first two years of the disease. The innocent party can hardly escape if the patient has open sores in the mouth. It is probably particularly important not to kiss children for the reason that usually their mucous membranes are more tender than are those of adults.

While it is somewhat a matter of doubt as to how syphilis is transferred during sexual intercourse after the initial sore has healed, it is nevertheless absolutely certain that such transfer does occur. The patient should, therefore, be told that sexual intercourse must not be had during the first twelve or eighteen months or during any fresh outbreak of symptoms after a period of neglect of treatment, for the reason that he is then almost certain to bestow the disease upon the woman. To be the victim of syphilis is in itself a misfortune, but to transfer the disease to an innocent party is a base and cruel act.

The patient should be taught that all cotton, gauze, or other form of dressings which has been on an open sore may contain the poison of the disease in such a form as to transfer it to an innocent attendant or associate. Therefore all dressings which have been on open sores and wounds should be burned. Perhaps the best way to accomplish this is to drop the dressings into paper bags, close the bags in the usual manner, and throw them into the fire.

The patient should be told that, in general terms, syphilis is a parasitic disease and is, therefore, comparable in this particular with tuberculosis. He should also be informed that as in the case of tuberculosis the general strength of the patient must be kept up to the highest possible measure of good health by means of plenty of fresh air, regular habits of eating, sleeping, and exercise and abstinence from anything in life which tends to deteriorate the health. Explanation should also be given to the effect that, as in tuberculosis, the medicines prescribed partake almost of the nature of food-stuffs in combating the disease, and should, therefore, be taken with the greatest regularity and faithfulness, as is food itself.

It is also well to add that frequently, notwithstanding great watchfulness on the part of the physician, new developments or even complications may arise much as they do in the case of tuberculosis, and that it is the express duty of the patient to seek medical advice should any such seem to appear, and at the earliest possible moment.

The patient should also be told that disobedience to these general regulations in any particular will, on the whole, delay or even defeat his cure and may well be the means of spreading the disease to other people.

The fourth heading of the circular spoken of before is that the patient should understand that, although syphilis may be cured fully, it frequently leaves behind it certain tendencies, so that when later in life other diseases attack the system they are in turn affected by the fact that the patient has previously had syphilis. The victim of syphilis should, therefore, always tell any physician who is treating him for any other disease later in his life that he has had the syphilis, because this fact so often alters the treatment of the disease in question. It will, therefore, be entirely to his own benefit for the doctor to know all about his syphilis.

The third heading of such a circular mentioned above, namely, that concerning printed directions as to elements of treatment, such as inunctions, is discussed last for the reason that such directions had best be given in a separate circular, so that the patient will not be tempted to begin the treatment until the ripe moment under the doctor's directions, at which time he supplies the victim with this separate printed slip.

The following little circular has been found of much value at the author's clinics at the New York Hospital and the House of Relief for the purpose of preventing mistakes in giving inunctions. It is founded more or less upon a similar circular issued by the Vanderbilt Clinic:

Directions for Using the Ointment or Salve.—Always wash the skin and dry it carefully before beginning to rub.

Take only one measureful (a half-drachm or drachm measure should be supplied) of salve each night or every other night as directed by the doctor and change the part of the body for the rubbing from night to night as follows:

First Night.—Neck and head, excepting the scalp.

Second Night.—Right palms, forearm, upper arm, and armpits, avoiding the hairy part.

Third Night.—Left palms, forearm, upper arm, and armpits, avoiding the hairy part.

Fourth Night.—Right leg and foot, including the sole.

Fifth Night.—Left leg and foot, including the sole.

Sixth Night.—Right thigh with the groin.

Seventh Night.—Left thigh with the groin.

Eighth Night.—Chest.

Ninth Night.—Abdomen or belly.

Tenth Night.—Right side of back from the root of the neck to the lower part of the gluteal region.

Eleventh Night.—Left side of back from the root of the neck to the lower part of the gluteal region.

Syphilis is, fortunately, a curable disease if the

patient has no taint, such as tuberculosis and no vicious habits, such as alcoholism.

The reason why syphilis is so hard to cure in most patients is that they will not submit to regular, unbroken treatment for two or three years. Without such treatment a cure is not possible. When the outward or visible signs of syphilis which attract the attention of the patient have disappeared (as they always and quickly do under a few weeks' treatment in skilled hands) most victims of the disease cease treatment, fancying that they are cured. Later, however, the signs return invariably and then in more obstinate and intractable forms. Such relapses are the fault not of the doctor and his treatment, but of the patient in discontinuing the treatment of his own accord, and in ignorance of the dangers of these relapses and of their certainty to occur after neglected treatment.

If, as Prof. Fournier says, syphilis is probably on the increase in all walks of life, is it not high time that in syphilis, as in tuberculosis, the medical profession in its public and private practice spare no effort in time and labor to bring about such understanding among the laity as will itself minimize the dangers of this scourge of humanity, syphilis, to innocent persons, who, according to Fournier, so far as women are concerned, number 45 in 887 cases reported, which is more than 50 in 1,000?

In the experience of the writer in the past three or four years this circular has been a step in the right direction along these lines, and it is hoped that these brief comments thereon will induce others to try them and similarly to be benefited by them.

The following is the epitomized form of the above discussion, which occupies a sheet 5 inches by 10 inches.

This disease is called syphilis, syph., pox, great pox, lues, or "blood disease"—all these terms meaning the one and same thing. Syphilis is a treacherous and dangerous disease of the entire system and requires for perfect cure at least two, better still, three years of faithful treatment, because it is "in the blood." Healing the chancre and taking medicine for a *few weeks or months* will not cure your blood of the syphilitic poison. It is, therefore, necessary that you follow the doctor's orders most carefully. If you do not you are in danger of having the disease appear in the future in some important part of the body, like the brain, spinal cord, bones, arteries, or other organs, as the liver. If you do not follow directions it is also possible that your wife and children will acquire the disease from you.

The following directions are of particular importance during the first year and whenever, if you neglect yourself, the symptoms break out again:

Intoxicating liquors in all forms must not be taken, because alcohol is a poison which, added to the poison of the syphilis, makes the syphilis much less likely of perfect cure.

Do not smoke or chew tobacco, because the irritation of the tobacco increases the severity and duration of the mouth sores of syphilis.

Sour, acid, peppery, and spicy foods and pickles should be avoided for the same reason.

Brush your teeth and wash your mouth every night and morning. Cleanliness of the teeth and mouth decreases the severity and duration of the mouth sores of syphilis.

Allow no one else to use your tooth brush.

Have a dentist treat your teeth, if they are bad. Tell him at the first visit that you have syphilis, so that he may take precautions against catching the disease himself and giving it to other patients by instruments used for you.

To prevent giving the disease to your family, friends, and associates, observe the following rules strictly:

Always sleep alone.

Always use only your own toilet articles, such as towels, brushes, combs, shaving brushes, razors, soaps, etc.

Always keep only for your own use any article which has been in your mouth, such as tooth brushes, tookpicks, pencils, pipes, cigars, cigarettes, forks, spoons, cups, etc.

Always avoid kissing anyone, especially children.

Sexual intercourse must not be had during the first year and during any fresh outbreak after neglect of treatment, because you are then certain to give the disease to the woman.

Always burn dressings which have been on open sores or wounds.

If you disobey these directions you will certainly give the disease to innocent persons.

You should always tell any doctor who is treating you for any other disease in the future that you have had syphilis, because this fact often alters the treatment of the disease. It will, therefore, be entirely to your own benefit for the doctor to know about your syphilis.

Syphilis is, in persons who are otherwise strong and healthy, nearly always a fully curable disease, so that you may have good hopes of perfect cure, only provided, however, that you continue faithful and careful treatment in skilled hands for at the very least two years.

45 West Ninth Street

THE DETERMINATION OF SEX.

By ARTHUR H. JACKSON, M.D.,

LOS ANGELES, CAL.

Since the earliest dawn in the study of embryology, pertaining to the development of the human embryo, scientists have been confronted with the great question: "The cause of the sex."

With the advance of the microscope a great deal of investigating work has been done, which enables us to form a clearer perception of the development of the ovum in its various stages. But the vital question is still to be solved. A good many theories, however, have been brought forward. Some are based on careful research work, while others are merely idle dreams. To the latter belongs the method of Dr. Schenk, who advocated a certain diet for the mother as a means to control the sex of the fetus. This theory for a while gave considerable notoriety to the author, but proved a great disappointment to the dieting mothers, and the theory soon proved itself false in principle. Physiologists, however, have not yet abandoned hope. Investigation still goes on; the microscope is still in use, the ovum is being carefully observed, and we are still looking forward to the day when the sex of the child will be under the control of the parents.

Science has made wonderful strides in the last century, great problems have been solved. Bacteria have been grouped into different families and their mode of reproduction demonstrated. The individual human cell has been measured and chemically analyzed; physiologists know exactly its constituents, the size of the neuclei, the amount and color of its protoplasm; but the great factor which causes the cell to develop, to multiply, to change its shape, is as much of a mystery to us to-day as it was in the dark ages.

It is not my aim to deny the scientists the merit of their great achievements while they are trying to

solve the mysteries and forces which govern Nature's laws, and science needs no apology, for it has shown us the forces that are at work, and has opened up the way by which we may continue to study these great questions. So it is with the sex question. While we may not be able to control it, yet it seems to me that with all the investigations made by embryologists, which work is still, I may say, in its embryonic stage, we ought at least to be able to build up a theory which may guide us in our reasoning whereby we can watch the causes of the sex development as Nature sees fit to determine.

After all, a good plausible theory is considered almost a fact by the well-developed and enlightened minds of the present day. Where would the laws of chemistry stand if they would not have for their foundation the atomic theory? Ehrlich has recently revolutionized our conceptions of immunity by his masterful side-chain theory, which, while it is by no means demonstrable under the microscope, is accepted as most plausible.

The sex question is by no means devoid of its reasonable theories. However, as they stand now, there seems to be considerable inconsistency between them.

I shall not attempt to discuss all the theories concerning the sex question in this article, but it is my aim to elaborate on Minot's theory, which may eventually lead us to the right path of reasoning, and prove to us that the sex factor is beyond our control, even if we do know the processes the ovum undergoes during the various stages of development. But before we can deal with the ovum as the determining factor, we must discuss the rôle the spermatozoon plays in determining the sex of the offspring, as many still claim that the spermatozoon is a predominating factor. Among those who adhere to this theory are Hofacker and Sadler, who claim that the superiority, mental and physical, of the male will tend to reproduce its own sex. This is true enough as to reproducing itself, but this does not necessarily affect the sex individual, since the paternal traits evidence themselves in the female as well as in the male offspring. This alone would prove the theory unreasonable as to the tendency of the male to reproduce his own sex. From every-day observation we can further reason, and it is not necessary to quote statistics, that women may have children by more than one male, yet all to be of the same sex. This would lead us to reason that the male is not the determining factor. With all these facts and reasoning we have ample ground for abandoning the theory that the male is a factor in sex determination. However, it is proven that it is essential in the process of generation to have a spermatozoon which unites with the female pronucleus, and causes what we call life to begin.

Now, since we may reasonably exclude the male as a sex factor, we must return once more to the ovum for the determining factor in the sex question. The same view is held by a good many authorities on this subject. Lenhosseck attributes the sexual differences to the unfertilized ova. Prof. Schultz of Jena contends that the ova have definite sex, male and female. From this we would have to reason that the fate of the sex would depend on the ovum which becomes fertilized. This may sound plausible, but yet it seems that nature would decide the sex on a more definite basis, and from careful observation of the development of the ovum in its process of maturation, I am inclined to think that there is ground enough left to build up a more reasonable theory on a broader basis which will throw more light on the sex question.

It has been observed that two polar bodies are formed from the ovum during its processes of maturation. This takes place while the ovum is still in the graafian follicle. For this phenomenon a good many theories have been advanced. Hertwig says that maturation is a process of cell abortion and that the polar bodies are merely aborted cells. Minot claims that the polar bodies consist of the male element excluded from the ovum, which is at first in a hemophroditic state, containing both male and female elements, and fertilization can take place only when the male element is given off. We are forced to admit that Minot's theory is the most reasonable, for it is a fact that scientists have traced the highest form of animal life back to the hemophroditic state, in which both elements of regeneration were combined in one individual life. But in the constant struggle for the survival of the fittest, there came a division of the element forming the female and the male. Even at this late hour of evolution we can trace the analogy between the sexual elements of generation in which each became a different factor in the process of reproduction. Though they are analogous, each one is so shaped as to be able to perform the functions designated by Nature. Since they came from the same ovum, which has the same cell construction, we are led to believe that the ovum contains both elements. But since the division of the species into the two sexual elements is so definite, there must be a separation of the two elements in the ovum before it can become fertilized, for the spermatozoa, having an affinity for only one definite sex, cannot combine with both elements in the ovum. Hence the polar bodies excluded from the ovum can be reasonably accounted for as simply the element not destined for reproduction. It does not necessarily have to be the male element, as Minot claims, for why cannot the female be given off in the polar bodies, leaving the male element to become fertilized? The process by which the polar bodies are formed would favor this theory as to the division of the sexual elements, for it is not merely a division of the nuclei and the protoplasm of the ova, but is a distinct separation of the two elements gradually caused by direct cell division first forming one polar body, and then a second one completely separating the elements. If fertilization of the ovum could take place before the extrusion of the polar bodies, we would be inclined to reason that the spermatozoon is a factor in determining the element which should remain in the ovum, but since it is proven that fertilization takes place after maturation of the ovum, we must look for some other source for the factor which causes the elements to divide.

It would hardly be reasonable to think that the female has an influence in the division of the ovum, since it is known that her own will as to the sex of the future offspring cannot be gratified. This will exclude her nervous influence over the ovum, while her physical constitution can be seen in the offspring, independent of the sex which it may happen to be. Therefore, the mother as a factor will also be excluded. And now we must come to the ovum direct for the determining factor. In watching the forces which govern natural laws of evolution, we have observed that there is always a struggle for the survival of the fittest, from the highest to the lowest form of animal life. Why cannot the same struggle take place in the ovum, leaving only the fittest element to survive, while the weakest finds itself among the polar bodies, no matter what sex it may be, and the struggle for a future existence may as well begin in the individual cell as later in life.

Hereditary tendencies may play a prominent part which might influence the element. It can be seen that in some females the male element may predomi-

nate, while in others it is the female. Then we have females who reproduce nothing but females, no matter how many males may be the factors of fertilization of the ova, while others reproduce males. From this we can reason that in these instances one definite element is constantly predominating over the other, while in others the elements vary.

As to the ratio of births, statistics differ. Some claim that more females are born, while others claim the reverse. However, Nature never intended to put the birth rate on monogamistic laws, for monogamy is not the process of evolution but merely a factor in the history of the development of the human race. It has been proven that the female must predominate for the survival of the species, from the lowest to the highest form of animal life.

Natural laws can never be altered, no matter how we may try to shape the individual cell, no matter how we may try to oppose Nature's forces, the struggle for existence constantly goes on in spite of civilized methods and laws. Therefore, reproduction cannot be based or regulated by any set rules. It is Nature's own force. We can only study, reason, watch, and observe the forces as they are constantly shaping themselves so as to remain fittest in the survival of the great human race.

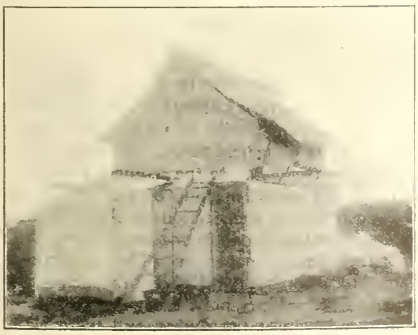
PHTHISIS TENT FOR OUTDOOR LIFE.

By NORBURNE B. JENKINS, M.D.,

NEW YORK.

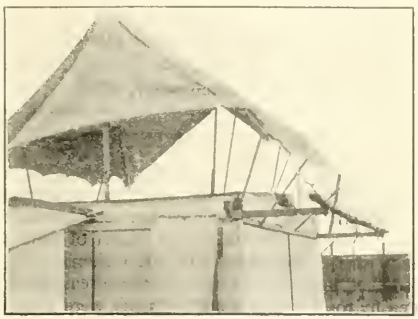
A TENT here illustrated may be useful for outdoor life and for the treatment of tuberculosis and other diseases. Owing to its elevation it is comfortable the hottest days and nights, for, with the walls and eaves propped up with sticks, only a large umbrella, as it were, is overhead. Air circulation is free, but within easy control. In rain the walls are lowered to overlap the top platform.

This tent consists of two platforms somewhat smaller than ten by twelve, a ten-by-twelve duck tent with a fly and three-foot wall, four eighteen-foot heavy upright posts planted eight feet, and some scantlings bolted to the posts to secure the platform and guy ropes. About eighteen inches is sawed off the tent poles.



The lower tent is made by encircling the upright posts with wide, heavy, unbleached sheeting secured by laths or furring, and here may be trunks, dressing room, and bath and toilet equipment. A stove below, with a pipe extending through the upper tent, can be used for heating. A kitchen may be annexed for modern oil stove and simplest cooking utensils. Such tent may be put up at a cost of thirty dollars and two days' work. Specifications are not given, for the carpenter, the fresh air advocate, and the consumptive, by mechanical ingenuity, may improve and simplify this crude affair.

On the top platform may be a fifty-pound mattress of goat's hair, sheets, pillows, and four or five heavy blankets—those made for race horses are recommended; they are the softest wool, sell for about



twenty-five dollars, and are of size to enwrap the patient, Indian fashion. Damp clothing and outdoor and downstairs' shoes are removed before climbing upstairs, where woolen shoes or one or more pairs of heavy wool hose are worn. Cool nights the head and neck may be protected by a wool bag or cap with an opening for breathing. At night may be worn a suit of wool of weight suitable to the temperature. It should be one or two sizes too large and made soft and comfortable by laundering. Cast-off suits may be used. Frosty nights some wear overcoats. Comfortable and protective clothing at the expense of fashion should be selected and adapted to the individual. Skin and circulation should be free and untrammeled.

Sleep may begin at dark and end at sunrise. Naps through the day are advisable if insomnia is not caused thereby.

Mouth breathing in the open air may be injurious. It may be controlled sometimes by a bridle, illustrated in the MEDICAL RECORD, September 10, 1898, page 394. Neither the tent nor bridle is patented.

Changing radically the environment of the consumptive is often serious, but a necessity, and is as much an art as changing the environment of plants or animals, or putting into camp city-bred recruits. Consumptives, soldiers, animals, and plants may perish if handled radically and unscientifically.

Localization and Method of Development of Myomata of the Human Uterus.—Keiffer presents various cuts explanatory of his researches. Most of these illustrations argue neither for nor against Cohnheim's theory. As to the method of dissemination of young myomata in the uterus, the writer has been impressed by the relationship which exists between the position of these tumors and the direction of the uterine vessels. From these preparations it would seem that myomata may develop in various parts of the uterus where they show the characteristics of simple myomata, of fibromyomata, of limited, encapsulated, or diffuse myomata, according to the special localization of the tumor, the method of evolution, whether this be by simple muscular proliferation, by reaction more or less intense of that part of the muscle layers surrounding the primary nucleus, or by the reactional development more or less intense of that part of the vessels which surround the primary nucleus. The development, increase, and nutrition of these tumors cannot go on without the formation of new capillaries depending upon preexisting vessels. The method of vascularization of young myomata has a very important influence upon them.—*La Gynécologie.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE

New York, September 7, 1907.

THE ARMY CANTEEN.

THE perennial question of the army canteen is beginning its autumnal recrudescence with the reports of the commanding generals of the departments of the U. S. Army. In the annual report of General Greely of the Department of the Columbia, it is stated that fully 80 per cent. of the offenses committed by the soldiers in his command were directly traceable to the evil influence of the saloons grouped around the army posts. "It is beyond reasonable doubt," Gen. Greely says, "that the establishment of the canteen decreased drunkenness in the army and that its elimination has largely increased liquor drinking and dissipation among the enlisted men. Without exception, the company officers who have been habitually questioned on this subject state that the restoration of the canteen would benefit the army both morally and physically." Gen. Funston of the Department of California, Gen. Grant of the Department of the East, and the Judge Advocate General of the Army all bear testimony to the same fact that the canteen would, as it did, "promote discipline, discourage gaming and squandering, conserve health, and thus be to both the material and moral interests of the enlisted men."

But all this expert testimony, unimpeachable as it is, will probably have as little weight with Congress during the coming session as it has had in the past, and the dives outside the army posts will continue to thrive under the protection of the temperance women who have terrorized the national lawmakers. Senator Warren, chairman of the Military Affairs Committee of the Senate, is quoted as saying that he finds a steadily growing sentiment among the officers of the army, and the people at large, in favor of restoring the army canteen, but has nevertheless little hope that they can get such a measure through any time soon. "You see," he added, "the good women have got it into their pretty heads that the canteen is a thing of the devil and that it makes a gin mill out of every army post, and these good women have blown up such a wave of reform that representatives of the people are afraid to run counter to it."

The foolish suggestion has been made that the Government should compel the enlisted men to abstain from the use of alcohol at all times, just as the railroad companies demand total abstinence of their employees. The good but impractical persons with this bright idea ignore the vast difference that there is between the well-paid railway employees and the poorly-paid soldier, who would often welcome a discharge if he could get it. A locomotive engineer is content with his job, and willingly accepts the condition of abstention from alcohol which is associated with the responsible position he holds, but it is difficult, in time of peace, to secure men who are physically fit for the army. Those who are acquainted with the prevailing conditions say that it is becoming increasingly difficult to obtain enlistments and prevent desertions, and that one of the chief deterrents of those who think of enlisting is the belief they will be deprived of what they regard as one of their rights.

Another of the unanswerable arguments of the active opponents of the canteen is instanced by Senator Warren. "Some of the women ask me," he said, "if I want a boy to be brought up in a gin mill. When I reply that it is far better that they be allowed to buy and drink light beer in a decent, respectable place inside the lines under regulations than to frequent the dives on the outside, where the worst of vices prevail, they reply: 'Well, no well-brought up boy will go to those places, anyway.'" There is nothing to be said to that, and so the poor Congressman finds it easier to shrug his shoulders and promise to vote against beer in the post exchange, and incidentally for the perpetuation of the dives outside.

THE MILK SUPPLY OF ENGLISH TOWNS.

WHILE New York, with a comparatively good milk supply, has been clamoring for a purer one, London, with far more reason for complaint, has only begun to wake up to the dangers of bad milk. Although the lay journals of London have not been so conspicuous in their demands for radical changes in the control and management of the milk supply as the journals of New York, yet much has been written of late urging a close investigation of the London milk question. Among the British medical journals, the *Lancet* has been to the front in showing up the defects of the present system of supplying milk to London, and a series of convincing articles have been written in that journal dealing with various phases of the matter. Undoubtedly, nothing but good can come from the ventilation in the press of the situation as regards the milk supply in London, for once the general public becomes really interested in the matter, and demands a pure milk supply, such a supply will be forthcoming.

That there is a very intimate connection between infant mortality and milk is a point that requires no argument in a medical paper. What is needed is to drive this fact home to the mothers in the great cities. At the recent meeting of the British Medical Association, in the Section on State Medicine, Professor Kenwood, one of the best known British authorities, read a paper on "The Reduction of Infant Mortality by the Better Management and Control of the Milk Supply." He pointed out that the danger began at the source, and there was no doubt of the appalling ignorance which prevailed on dairy farms. To those who were acquainted with the methods pursued in Denmark, the conditions prevailing in England were absurd and horrible, and the milk reached the distributer in a state of absolute filthiness. Professor Kenwood said that the regulations controlling the milk supply of Great Britain were notoriously defective and

inadequate, but even these were not acted upon properly. It was, therefore, evident that some compelling statute was required and that proper Government supervision was quite as necessary as it was in the case of the adulteration of food and drugs. Milk shops should be licensed, not, as at present, simply registered. The systematic inspection of milch cows should be made at intervals of not less than three months by a veterinary inspector under the Board of Agriculture, and tuberculous animals should be segregated and slaughtered. Professor Kenwood, in discussing the pasteurization of milk and the compulsory sale of milk in bottles, said that by such means much of the home contamination of milk might be avoided, while the bottle was a guarantee of full measure and watering was rendered less easy. He considered that the dangers arising from feeding infants on sterilized milk had probably been exaggerated.

It has been pointed out on previous occasions in the MEDICAL RECORD that the conditions in London as regards the milk supply are far worse than those which prevail in New York, but that the conditions in New York are susceptible of much improvement. When the milk supply is good, infantile mortality is low, and *vice versa*.

INDIGOCARMINE IN THE DIAGNOSIS OF THE KIDNEY FUNCTION.

THE successful treatment of surgical diseases of the kidneys rests on an adequate determination of their structural and functional conditions. One must know exactly whether both kidneys are diseased, or whether one only is diseased, and, if so, which one. When one only is involved, we must know whether the function of the other is sufficiently good to permit the performance of a nephrectomy upon the diseased organ. It is therefore of great importance to obtain the excretion of each kidney separately and to ascertain the functional capacity of the healthy kidney. Various methods have been employed to ascertain the latter, some of which, such as the complete chemical examination of the blood and urine are too complicated for general use, while others, such as the microscopical examination of the urine and the estimation of the total amount of urine and urea excreted do not give us sufficient information. Cryoscopy is not always reliable, and requires considerable practice. Much simpler and quite reliable methods are those which depend upon the excretion of substances injected subcutaneously, such as phloridzin and indigocarmine; they are easily detected in the urine and are almost exclusively excreted by the kidneys.

In the *Correspondenz-Blatt für Schweizer Aerzte* of August 1, 1907, Dr. F. Suter reports thirty-seven cases of unilateral kidney disease, in which the indigocarmine test was employed before operation in order to ascertain which kidney was diseased and whether the functional capacity of the other was sufficient to carry on the vital functions. After an intramuscular injection of four c.c. of a four per cent. solution of indigocarmine, the bladder was washed with a solution of boric acid and a Luys segregator introduced. The urine from the kidneys was collected simultaneously for twenty or thirty minutes, this being necessary, as only comparative values have any significance. In individuals with healthy kidneys, ten to twelve minutes elapsed before the excretion of colored urine began. In Suter's series of thirty-seven cases he always found it safe to remove the one kidney when the indigocarmine had begun to be excreted in ten to twelve minutes by the other. The greater or less intensity of the blue was also found of value when the urines of the two sides were compared; a deep blue color was a sure sign that the kidney was healthy, but when the urine was of light blue color he depended more on the time which elapsed before any colored urine was excreted. In twenty patients no colored urine was secreted by the diseased kidneys, and these after removal showed no normal tissue. In thirteen patients colored urine was excreted by the diseased kidney anywhere from five to twenty minutes later than by the healthy one; this urine was also of a lighter blue. In three cases blue urine appeared simultaneously at both ureteral orifices, but that coming from the healthy organ was of a much deeper hue. As a rule, the longer the time before colored urine was excreted and the less intense the blue, the greater was the pathological change in the kidney. The majority of the diseased kidneys removed were tuberculous. In all, thirty-five nephrectomies and two nephrotomies were performed with no deaths, as a result of the operation, or soon after the latter, from insufficiency of the remaining kidney, a sure proof that the indigocarmine test is of value in estimating which kidney is diseased and whether the remaining kidney is able to maintain the vital functions. In eleven other patients renal insufficiency was diagnosed on both sides after the injection of indigocarmine, and consequently no operation was performed; eight of these died shortly afterward with uremic symptoms, another proof, the author maintains, that the method is reliable.

While Suter believes the indigocarmine test to be the simplest and most reliable of the various methods used in ascertaining the capacity of the kidney function, he does not underestimate the value of the other clinical methods, some of which he always employs in conjunction with the indigocarmine test.

VARICOCELE AS A SYMPTOM OF MALIGNANT KIDNEY TUMORS.

THAT malignant tumors of the kidney can cause a varicocele on the affected side has been known since the times of Guyon, who laid especial emphasis upon its diagnostic value, and his observations have been confirmed by Israel, Schede, and Küster. Recently, J. Hochenegg (*Zeitschrift für klinische Medizin*, Vol. 62, 1907) has again drawn attention to the diagnostic and prognostic value of a symptomatic varicocele, and has shown how it may be differentiated from the ordinary idiopathic variety. The latter usually occurs in young adults and causes greater pain. With the patient in the standing posture both present the same appearance, but when he assumes the dorsal position the idiopathic variety always disappears, while the symptomatic varicocele remains unchanged, and at times even becomes more prominent. Hochenegg explains this difference by the fact that in the former there is no hindrance to

the flow of blood from the spermatic vein, while there is in the latter variety.

In one patient the impediment to the flow was caused by an extension of the growth into the renal vein beyond the point where the spermatic empties into it; in another by the pressure of enlarged glands. Another time the tumor itself compressed the spermatic vein, the possibility of which occurrence explains the fact that the varicocele is sometimes made more prominent by placing the patient on his back. In a fourth patient the kidney had descended as a result of its increased weight, thus causing a kink in the vessels. When the varicocele was caused by a sharp curve in the vessels or by direct pressure of the tumor, it could be made to disappear by raising the tumor, or by placing the patient in the knee chest position; when due to an extension of the growth into the renal vein, or to pressure of glands, it could not be made to disappear. This differential point in regard to the etiology of symptomatic varicocele is of prognostic value, as cases with an extension of the growth into the renal vein, and those in which the glands have already become involved, are usually inoperable. Thus, too, the return of the varicocele after nephrectomy may be the first sign of secondary glandular involvement. As regards the frequency of this condition, older statistics on kidney tumors are of little value, as no attention was paid to the presence of a varicocele. Hochenegg observed it in six out of sixteen patients with malignant growths of the kidney. In one case a renal tumor was unsuspected, and the author's attention was drawn to it only after the symptomatic varicocele had been diagnosed.

Malignant growths of the kidney may be suspected when a solid tumor can be felt in the region of the kidney, when the urine contains blood and particles of tumor tissue, or when the patient complains of constant pain in the lumbar region; yet all these symptoms may be absent, even in inoperable tumors. The sudden development of a varicocele, occurring late in life, should, however, always lead one to suspect a renal tumor.

The Clinical Value of Serum Diagnosis in Syphilis.

The phenomenon of fixation of complement has been well known since Bordet and Gengou demonstrated that complement added to a mixture of inactivated bacteriolytic serum (antibody) and bacteria (antigen) would not produce hemolysis when sensitized erythrocytes were subsequently introduced. It remained for A. Wassermann to show that extracts of the infecting organism could be used instead of the pure culture of bacteria, which thus enabled us to investigate infectious diseases whose exciting organism could not be grown in pure culture, syphilis being foremost among these. The phenomenon is based upon the fact that the union of antigen and antibody has a great affinity for complement, and binds the latter to themselves. That is to say, if an extract of a luetic liver is brought together with syphilitic antibodies, such as are found in the milk, spinal fluid, and serum of syphilitic patients, complement will be bound to these two, while if the extract is added to the serum of a nonsyphilitic person complement will not be fixed. In other words, if complement is fixed we can say that the added serum contained syphilitic antibodies, and thus syphilis can be diagnosed according to some investigators. In order to ascertain whether complement is fixed or not, a hemolytic serum is used as an indicator. As hemolysis takes place only in the presence of complement, we can tell by its occurrence that complement is free and not fixed; in other words, when hemolysis sets in it shows that the serum contained no antibodies, while if there is no hemolysis complement has become fixed, this proving the presence of antibodies. In the *Deutsche medizinische Wochenschrift* of August 8, 1907, M. Wassermann and G. Meier report their results in a number of cases in which they tried to diagnose syphilis by the method of fixation of complement. They claim that these were entirely dependent upon the methods used in the test, and that certain conditions must be fulfilled before the results can be called reliable; these include the preparation of the antigen, complement, hemolytic serum, together with ten control tests, all of which they describe in detail. They examined thirty-nine cases, some of them clinically doubtful cases of syphilis, others clinically certain cases; twenty-seven positive and twelve negative reactions were obtained. The positive ones included cases of tabes, dementia, meningitis, and aortic aneurysm, three times the syphilitic antibodies were found in the milk of puerperal women, once in the serum of a fourteen-days'-old infant with all the clinical signs of congenital syphilis. Wassermann and Meier claim that their examinations show that in certain cases specific substances are found in the serum of syphilitic patients, but that it is still uncertain whether these are the immunizing bodies of syphilis. They furthermore believe that the diagnostic value of this reaction is uncertain, as the number of cases examined is still too small, but that it has a probable future in the diagnosis of syphilitic diseases of the central nervous system, circulatory system, liver, etc.

Another Theory of Appendicitis.

When appendicitis was first recognized in America it was regarded by most of our European confrères as a figment of the Yankee brain or as an invention for the despoiling of trust magnates and the gathering in of twice-tainted money. Writers on intestinal diseases treated it with about as much respect as Möbius did another American discovery when he dismissed eyestrain as a cause of headache with the remark that this was a cause which appeared to be epidemic in the United States. After a while, however, when royalty began to have it, foreign practitioners were forced to admit its existence, and the surgeons even began to operate for its relief. Now that it has been admitted to the list of recognized diseases, the question of the etiology of appendicitis is being discussed with interest. At first the chronological argument seemed to be the only one of importance, and one custom or habit after another which happened to originate about the time appendicitis began to be diagnosed has been credited with causing it; one writer in an English journal even hazarded the guess that cigarettes were at fault, since the habit of smoking them came into fashion along with appendicitis. Although it is comparatively seldom that foreign bodies are found in the inflamed appendix, some surgeons cannot disabuse their minds of the notion that there must be some extraneous substance to account for a catarrhal inflammation of the mucous membrane of the appendix. The most recent conjecture is one expressed in a clinical lecture delivered at St. Thomas' Hospital

by Mr. William Henry Battle, and published in the *Lancet* of August 24. This theory, which was regarded as so startling in its nature that it was at once cabled to this country, is credited by the lecturer to an American physician writing in an English paper. It is that appendicitis is due to the general use of American steel-rolled flour. Mr. Battle in accepting the theory is apparently also moved by the chronological argument. He says appendicitis first occurred in America just after steel and iron rollers had been introduced for grinding wheat. The increase in appendicitis occurred first, he says, in towns where rolled flour was first used. Then it spread to villages, and lastly to negroes, who earlier had escaped, and this spread corresponded with the spread in the use of rolled flour. An invasion of England followed. This, of course, explains why the disease was so long in gaining recognition in England and on the Continent, for of course it could not be recognized until it existed, and it could not exist until the metallic particles in American steel-rolled flour got into the appendix. The discovery of the cause will doubtless simplify the treatment, for all that will be necessary in the future will be to draw the steel out of the appendix by means of an electromagnet and so avoid a cutting operation.

News of the Week.

The Plague.—Since July 18 eleven cases of bubonic plague have been discovered in San Francisco, and eight deaths have occurred. One of these deaths was at Berkeley, across the bay from San Francisco. The Board of Health will fumigate the city and county hospitals, and a regular inspection is being made of all coasting vessels. The war against the disease is prosecuted with energy under the system adopted last week, by which the city is divided into twelve districts, each in charge of a physician, inspectors, and assistants. This and other precautionary measures will be pressed vigorously while the outbreak lasts. A case of the disease was found among the crew of the mail steamer *Sierra*, which arrived at Honolulu on August 31.

Typhoid Fever in Chicago.—The activity of typhoid fever in Chicago now appears to have reached its height. This is the season of the year when typhoid fever is most in evidence. The Bulletin of the Health Department says that in Chicago from 1890 to 1907 more deaths from typhoid fever occurred during the month of September, but for a period of forty-nine years September leads August in the number of deaths from this disease. The number of deaths from typhoid fever so far this month is 42. The total number of the entire month last year was 29. An investigation of the cases reported shows that fully 50 per cent. have been away from the city just previous to the attack either on vacations or business trips. Last year it was found one-third of all the cases came from outside the city.

Yellow Fever in Cuba.—The yellow fever situation at Cienfuegos has improved. The last soldier to have the disease was discharged cured on August 28, though there are still a few cases among civilians. A case of the disease has been discovered at a place across the bay from Havana.

The Cuban Sanitary Board established by a recent decree of Governor Magoon will consist of one chief and a national board of five members holding office for four years.

Cholera is spreading among the Chinese in the lower Yang Tse ports. About 200 deaths are reported daily at Wu Hu and Kiu Kiang.

Health Conditions on the Isthmus.—The report of Col. Gorgas, Health Commissioner of the Canal Zone, for July states that there were only 1,007 cases of illness among the 38,000 employees, and that the mortality rate showed a reduction of 50 per cent. below that of the corresponding month of last year.

Guarding against Typhoid Fever at Jamestown.—The Chief Surgeon of Camp Captain John Smith, at the Jamestown Exposition, has issued the following instructions for the guidance of the officers and soldiers: "The presence of typhoid infection, both in and around the Exposition grounds, and its entrance into both the cavalry and infantry camps, make it necessary to take extreme measures to guard the camp from sickness and death. (1) No soldiers will be permitted to enter the 'Pine Beach District,' *i.e.* west of Maryland avenue and north of Ninety-ninth street, and commanding officers will send patrols at proper intervals to compel obedience to this order. (2) Officers and soldiers will eat and drink only at their messes or clubs. This does not apply to dinner invitations outside the grounds and beyond this vicinity, but in such cases it is presumed extra care will be taken to avoid dangerous foods. (3) No fresh milk, cream, or ice cream will be introduced into camp. (4) Only cooked or sterilized foods will be served at messes, excepting such articles as fruits with rinds or skins, and such vegetables as can be scalded before serving. (5) The same routine as to scalding kitchen and table ware will be observed as in the presence of cholera."

First Aid Chests in Factories.—A new law went into effect on August 1 in Massachusetts, which requires that in every factory or shop, in which machinery is used for any manufacturing purpose, there shall be kept "free of expense to the employees such a medical and surgical chest as shall be required by the local Board of Health of any city or town where such machinery is used, containing plasters, absorbent cotton, gauze, and all other necessary medicines, instruments, and other appliances for the treatment of persons injured or taken ill upon the premises."

Cultivation of Fenugreek.—It is reported that the Secretary of Agriculture has decided to make an experiment with the cultivation of fenugreek in certain of the arid lands of Texas. The seeds of the plant are credited with the property of promoting the assimilation of fatty foods, and on this account have recently been recommended in the treatment of tuberculosis. It is little used in medicine here, but is an ingredient of most "condition powders" for horses and cattle. It is official in the German Pharmacopœia under the name, semen fœnugræci. It is said that the young women of Tunis resort to fenugreek to increase the fat, which is there regarded as an essential in the factors which make for beauty in the female sex.

Nut Poisoning.—There was recently an epidemic of gastric troubles among the children of South-East London, which was traced to the eating of "Kaloo" nuts, a quantity of which had been brought in a vessel from the East and had been distributed among the costermongers of that part of London. Those who ate the nuts were seized very shortly afterwards with violent vomiting comparatively free from pain; the vomiting persisted for an hour or two after ejection of the partly-digested nuts, and by next day the patients seemed quite well. The vomit itself was bile-stained, but contained no blood; intestinal symptoms were few or absent. As

soon as the cause of the trouble was known, the authorities seized all of the nuts they could find, and destroyed all but a few that were kept for analysis. It is not known what the principle was that caused the symptoms of poisoning. The nuts were from a species of *Aleurites*, the genus to which belong the candleberry tree and the Chinese varnish tree.

Medical Fees in Germany.—The High Court of Germany has decided that it is illegal for the physicians of any locality to band together and establish a definite code of fees for professional services. The court took the highly complimentary but unsatisfactory ground that physicians were actuated by a desire to benefit their fellows, and did not expect to be paid the full value of their services. They stood above the level of men in business pursuits, and the establishment of a fixed fee for their services would lower their dignity.

Automobile Accidents.—The *New York Times* has collected reports of 96 automobile accidents occurring during the months of June, July, and August. In these 50 persons were killed and 202 injured. Of the accidents, 29 were due to driving at reckless speed. The papers of September 2 reported six accidents in the vicinity of New York, in which 4 persons were killed and 10 seriously injured.

Dr. J. C. Wallace of Arkadelphia, Ark., has been appointed by the Governor to fill the vacancy on the State Medical Board caused by the resignation of Dr. R. A. Hilton of El Dorado.

International Tuberculosis Congress.—The United States Government has officially invited Professors Metchnikoff, Calmette, and Letulle of Paris to take part in the deliberations of the Tuberculosis Congress in Washington in 1908.

The Michigan State Tuberculosis Sanatorium at Howell was opened on August 19 with seven patients. The Board of Governors has accepted the buildings now completed, and arrangements are being made to erect another building at once.

New Isolation Hospital for Chicago.—Health Commissioner Evans has formulated a plan to build a new contagious hospital for Chicago which will accommodate 240 patients, and to cost approximately $25,000.

Chicago School Inspectors.—A Civil Service examination was recently held in Chicago for school medical inspectors, and of 412 applicants examined, only 58 made a passing grade. Only one woman physician passed.

The Illinois Medical College conferred the degree of Doctor of Medicine on nine graduates, August 29, at the thirteenth annual commencement exercises held at Handall Hall. The degrees were conferred by the president of the college, Dr. H. H. Brown. The doctorate address was delivered by the Right Rev. Samuel Fallows, who selected for his subject, "The Relation of Religious and Medical Science."

Gift to a Willimantic Hospital.—The new St. Joseph's Hospital in Willimantic, Conn., has received a gift of $5,000 from an anonymous donor.

Gifts to Charitable Institutions.—By the will of the late A. H. Houseman, $10,000 is given to Mt. Sinai Hospital, $5,000 to the Hebrew Benevolent Orphan Asylum, $2,500 to the Montefiore Home, and $2,500 to the Home for Aged and Infirm Hebrews.

Obituary Notes.—Dr. George Waldron of Rochester, N. Y., was instantly killed in an automobile accident on August 28. He was a graduate of the Medical Department of the University of Buffalo in the class of 1881.

Dr. George Willis Benedict, formerly a practising physician in South Norwalk, Conn., died suddenly of disease of the heart on August 23. He had been in poor health for about a year. He was born in South Norwalk in 1852, was graduated in arts from Yale College in the class of 1874, and in medicine from the University Medical College, New York, in 1877. For four years he was postmaster at South Norwalk.

Dr. Henry E. Cushing of Champaign, Ill., died August 11, of pneumonia, at the age of fifty-three years. He was born in Asburnham, Mass., and was graduated from the Medical Department of the Northwestern University, Chicago, in 1884.

Dr. Benjamin Kittleman of Des Moines, Ia., died August 19, of pulmonary tuberculosis, at the age of thirty-one years. He was a graduate of the Medical Department of Drake University in 1901, and a year later was appointed treasurer in pathology in the Dental Department of the University.

Dr. Harry Coons of St. Louis died at the City Hospital there on August 19. He was born at Harper's Ferry, Va., on October 20, 1840. He served in a Missouri regiment during the Civil War, and at its close took up the study of medicine, graduating from the Medical Department of Washington University in 1870.

Dr. Adolph Hess of Milwaukee died on August 20, at the age of 42 years. He was a graduate of Jefferson Medical College in 1903. He was prominent as a Zionist, and was a leader in all movements looking to the betterment of the condition of Hebrew immigrants in this country.

Dr. L. L. Jones, formerly of Kansas City, Mo., died on August 13, at the age of eighty years. He was born in North Carolina, and practised in Kansas City from 1858 to 1861, when he removed to Gallatin and afterward to Linden in Clay County, Mo. He was a charter member of the first medical college organized in Kansas City. For many successive years he was president of the Clay County Medical Society.

Dr. G. Parsons Clark, dean of the College of Medicine of Syracuse University, died suddenly of heart disease on September 1 at his residence in Syracuse. He was fifty years old, and was graduated from Williams College in 1877 and from the College of Medicine of Syracuse University in 1880. He had been connected with the College of Medicine since his graduation. Dr. Clark was a member of the American Physiological Society and of the American Microscopical Society.

Dr. Augustus Coe Van Duyn, ex-Surgeon in the United States Army, died at his home in Kansas City, Mo., on August 28, from Bright's disease, aged seventy-four years. He was born in Romolus, N. Y. He entered the army at Jefferson Barracks, Mo., in 1863, and was mustered out with the rank of brevet lieutenant colonel.

Dr. John Elliot Miller of Hagerstown, Md., died suddenly on August 25 from apoplexy. He was born in 1837, and was graduated from the University of Pennsylvania in 1860. He served as surgeon in a Pennsylvania regiment during the Civil War. He retired from practice some years ago.

Dr. Isaac W. Herron of Charlotte, N. C., died on August 23. He was about seventy-five years old and had retired from practice. His four children, one of whom is Dr. Q. M. Merron of Charlotte, survive him.

Dr. Lansing B. Winne of Albany, N. Y., died suddenly on September 2. He was a graduate of the College of Physicians and Surgeons, New York City, in 1878.

SCHOOL HYGIENE—MEDICAL INSPECTION—MUSEUM TEACHING—HOUSING AND OTHER INTERNATIONAL CONGRESSES—MEDICAL MISSIONS—OBITUARY.

LONDON, August 17, 1907.

SCHOOL hygiene, from the point of view of the Second International Congress just concluded in London, is a much more extensive subject than the phrase suggests. No less than eleven sections struggled daily all the week with the numerous papers submitted. Some of these sections overlapped and the necessity of some others may be questioned, but a good deal of work was done. The spheres of the architect and engineer might as well have been left to experts, for although the building of schools, their sites, drainage, and ventilation are of no little interest to educationists, they can scarcely be entrusted with the duties of other professions. A twelfth section would have been more practical to some, viz., financial, on which the ratepayers should have been represented; for not a few members had ideas to enforce the value of which was less certain than the cost.

That medical inspection will in time be adopted by the legislature may be considered certain, for, in the words of Lord Crewe, the King's representative, "there cannot be two opinions as to its importance." This is generally regarded as a satisfactory result. But in view of some of the discussions the question of how it is to be carried out will give rise to misgivings. The teachers or some of their spokesmen seemed to be actuated by a desire to limit the inspection to the narrowest sphere. They would admit the Medical Officer of Health of the district to come in now and then, after due notice, at hours convenient to the teachers, and offer suggestions, and could even tolerate referring to his advice the question of closing the schools in an epidemic. Of course the Medical Officer of Health would not agree to be hampered in his duty if inspection were entrusted to him as he considered it ought to be. Thus in one discussion, at least, though the question was raised in several, it appeared to the onlooker that the Health Officers desired control over the hygienic arrangements and condition of all schools, while the teachers were most anxious to prevent any interference with their own supremacy. The boasted cooperation of doctor and teacher thus resolved itself in some cases into a distinct rivalry. Quite a number of teachers seem convinced that they are quite competent authorities on hygiene, and need only call in the Medical Officer of Health as a consultant on difficult problems. Some consider that a nurse might very well take the place of a medical inspector, as, for instance, by looking at the children's throats when a number complain of soreness. It was well that one speaker pointed out the futility of such notions, and told the congress distinctly that medical inspection must not be a sham, and should be entrusted to qualified practitioners, that at every turn questions would arise which could best be answered by the local medical man. Referring to the question raised in one section about outbreaks of measles, which some teachers had been speaking of as trifling incidents occurring in every child's life, he pointed out the enormous mortality and the sad sequelæ of this so-called "trifling ailment," and further showed that the general practitioner was the person most familiar with everything relating to it, and therefore the most competent to advise concerning it. Moreover, he said that instead of crushing him between the teacher and the Medical Officer of Health, every ailing child should be sent home with advice to its parents to call in their own doctor.

The breadth of view of the organizers of the Congress is illustrated by the inclusion of papers on the life of the children out of school, their play time and their games. Some would convert these into lessons and make physical culture a sort of additional school with its drill, exercises, gymnastics, dancing, and even jiu-jitsu—leaving, it would seem, no sphere for parental supervision.

The great importance of practical instruction was insisted upon in all stages of the Congress. In this respect of extreme interest was the appearance of Mr. Jonathan Hutchinson to urge the value of object-lessons and museums—a plan which has occupied him for years, and which he has carried out in professional teaching. He carried a resolution that systematic arrangements should be made for teachers and pupils to have constant access to well developed museums and other sources of knowledge, and another that provision should be made in all school buildings for the formation of an educational museum in which there should be displayed maps, models, portraits, pictures, natural history specimens, and scientific apparatus for objective teaching.

Mr. Hutchinson, true to his own teaching, invited a party of the Congress to inspect his own museum at Haylemere, where he entertained them with luncheon and tea and his own instructive and interesting remarks on the specimens, those of natural history including, I think, everything noteworthy to be found in one of the most delightful districts of the country. Since his retirement he has collected these and others and built a museum in which he gives demonstrations to the residents.

Sir Lauder Brunton, as President of the Congress, surpassed himself and must have felt the strain, although to the last he betrayed no fatigue. At the closing meeting he expressed satisfaction at the work they had done for the welfare of children, towards which everyone had aimed. One of the chief results of the Congress is the decision to establish a permanent council to deal with all matters concerning future assemblies—a kind of a clearing house of subjects relating to school hygiene, statistics, laws, regulations, etc. This council will consist of the president of the congress just held, the president of the next congress, and nine other members, to be elected—a permanent international committee, so to say.

The Housing Congress, also international, was, of course, largely concerned with public health, and papers interesting to doctors were submitted, but time and space forbid me to dilate upon them. It is proposed to hold a further conference by health authorities. What with conferences, congresses, and associations we have had such a full "dead season" that the tradition of such a thing is in danger. It has proved encouraging to the Esperantists, who met for their congress at Cambridge to the number of 1,400 from the many countries where it appears to have "caught on." The meeting of the International Association of the Medical Press must not be passed over without reference, for it initiated a movement which promises to have far-reaching results, in regard to secret medicines, advertisements, and testimonials. These delicate questions were discussed and some disciplinary measures determined on.

Medical Missions have sustained a great loss by the death of Dr. Sydney Rupert Hodge of Hankow. Educated at the Leys and Richmond College, he decided to be a medical missionary and entered the London Hospital, where he was a diligent student, and took the double qualification in 1886, going out to China the same year. The Hankow mission hospital was in a ruinous state, but he soon succeeded in getting it rebuilt and there he labored, with brief furloughs, until a dispatch announced his decease on the 21st ult. It was a great shock to his English friends, especially those who, like the writer, had watched his career and enjoyed his esteem throughout. To the poor Chinese to whom he sacrificed his life his loss is also a poignant sorrow.

Mr. Walter H. T. Brown, Consulting Surgeon to the Leeds General Infirmary, died on the 12th inst., aged 50. Two years ago he contracted septic poisoning, from a wound while operating. He was F.R.C.S.I., 1887. He had taken the English membership nine years previously, and served as house surgeon at the West London Hospital. Then he went to Leeds in a similar capacity, and has served the infirmary ever since. He also held other offices, and was a contributor of valuable papers to the societies and journals.

Dr. Robt. S. Archer of Liverpool died on the 8th inst., of diabetic coma. He was a Trinity College, Dublin, graduate; B.C., 1870; M.B., 1872; M.D., 1887. He spent most of his life in Liverpool, where he was highly esteemed; became secretary and vice-president of the Medical Institute, and was attached to the City Hospital, the Fever Hospital and other charities. He was author of "Smallpox: An Historical Sketch," and of many contributions to the journals and societies. He is said to have attended 2,000 cases of smallpox, and he gave valuable evidence to the Vaccination Commission.

OUR PARIS LETTER.

(From Our Special Correspondent.)

RADIOSCOPIC EXAMINATION OF TUBERCULOUS MEAT—FINGER PRINT IDENTIFICATION—EARLY DIAGNOSIS OF TUBERCULOSIS—TRAUMATIC ORCHITIS—NERVOUS COMPLICATIONS OF MOVABLE KIDNEY.

PARIS, July 15, 1907

AT the Académie des Sciences Martel suggested the use of radioscopy and radiography for the inspection of tuberculous meat. The tuberculous lesions of both the ox and the pig are commonly infiltrated with lime salts, and Martel has made use of this peculiarity in order to detect tuberculous foci in the depths of the tissues by means of the Roentgen rays. While healthy glands give only a very faint shadow on the radiographic plate, those invaded by the tuberculous process are projected in the form of a

granular shadow of greater or less extent, according to the degree of the morbid process. This new method of examination is valuable because by its means it is possible to detect tuberculous foci that were previously unsuspected. Martel stated that in this way it was easy to discover localized lesions quickly and that fat did not oppose any obstacle. He was of the opinion that in the large abattoirs the necessary apparatus could easily be installed so as to permit of the routine use of the method.

Dastre has reported to the Ministry of Justice the results of an investigation of the value of dactyloscopy, which is the method of identifying individuals by means of finger prints. He presented the conclusion that dactyloscopy, and particularly the study of the papillary lines of the finger tips, was perfectly reliable provided that several fingers were examined.

Roux has made public a method for the early diagnosis of tuberculosis. It consists in scarifying the skin and rubbing the wound with a tampon to which a few drops of tuberculin have been applied. If the individual is free from tuberculosis the little incision heals without complications, but if the reverse is the case a small pustule forms. Vallée of Alfort has found that this reaction also occurs in animals. In healthy cattle scarification of the skin and rubbing in the tuberculin produces no reaction, but if the animals are tuberculous an inflammatory dermatitis is caused which lasts for four or five days and then gradually subsides. Arloing declared before the Société de Biologie, however, that he had tried this procedure on nineteen animals, including calves, goats, rabbits, and guinea pigs, without being able to obtain a definite cutaneous reaction. The lesion produced was always limited to redness and temporary thickening of the edges of the scarification and these manifestations were observed in both the tuberculous and the control animals. He concluded that the cutaneous tuberculin reaction was unreliable.

Prof. Delorme presented before the Société de Chirurgie an interesting communication on the surgical treatment of wounds of the lung. He expressed the conclusion that in cases of pulmonary injury accompanied by severe hemorrhage it was dangerous to wait and that the formal indication was to check the bleeding. Two observations which he reported and which had been made by Ombredanne and Pierre Duval demonstrated that the risk of intervention in penetrating wounds of the chest had been greatly reduced and need no longer terrify the surgeon. The general condition is not very useful in estimating the gravity of the situation in serious cases, for there are no definite relations between it and thoracic lesions. Only the physical signs enable one to form an approximate estimate of the amount of blood poured out into the pleural cavity. These include hemoptysis, hemothorax, and external hemorrhage. The necessity for operation is determined by the total amount of blood that has left the vessels, and therefore a moderate hemothorax with abundant hemoptysis is as serious as a more extensive hemothorax alone. In continuing the subject Nélaton said that in exceptional cases when the patient's life was jeopardized by the abundance or the frequent recurrence of the hemorrhage, it was necessary to intervene and check the bleeding from the pulmonary wound. Unfortunately it was difficult to formulate the indications for surgical operative procedure, for both the general and the local signs were deceptive. What was going on in the interior of the thorax could be ascertained only from the patient's progress. Mauclaire reported an interesting case which he used as an argument for expectant treatment in pulmonary wounds. Reynier emphasized the excellent results that might be obtained by the use of hemostatics, such as gelatin solution, calcium chloride, etc.

An interesting discussion followed on traumatic orchitis. Felizet believed that there were undeniable cases of true traumatic orchitis and he reported four cases occurring in fencers as the result of a blow from the foil on the scrotum. These patients had never had gonorrhea. Routier, drawing on his own experience and on those of Terrillon and Monod, said that it was impossible to induce orchitis in animals simply by traumatism of the testicle unless the urinary tract had previously been infected. In all the cases of so called traumatic orchitis that he had seen he had been able to discover evidences of more or less latent gonorrheal infection. Prof. Delorme said that in his experience as military surgeon he had often seen, particularly among the cavalry, contusions of the testicle accompanied by more or less voluminous hematomas, but he had never observed true traumatic orchitis induced by the traumatism. When inflammation of the testicle resulted it was always in individuals exhibiting immediate or remote evidences of gonorrhea. Tuffier also said that he had seen contusions of the testicle simulating orchitis, but never a true traumatic orchitis. He considered that the existence of orchitis always indicated a previous manifest or latent infection of the posterior urethra.

In the Académie de Médecine Lucas-Championnière discussed the nervous complications of movable kidney. He said that these were very common and that they did not appear to result from disturbances of the urinary function due to ureteral kinking nor from displacement of viscera or enteroptosis. They seemed rather to depend on the traction on and stimulation of the suprarenal gland, whose functional importance had been emphasized by the advances of modern physiology. This new theory explains the extraordinary frequency of the nervous disorders accompanying displacements of the kidneys. These complications are, as a matter of fact, out of all proportion to the lesion itself, and it is well known that they may run the gamut from the most serious disturbance of nutrition, such as vomiting, weakness, and emaciation, to the gravest types of neurasthenia. The operation of nephropexy seems to be of service less because it raises up the kidney than because it fixes it and renders it immovable. The operation is therefore especially indicated when there are serious disturbances of nutrition and of the nervous system.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 22, 1907.

Torticollis: The Results of the Treatment of Cases of Acquired and Congenital Muscular Torticollis at the Boston Children's Hospital Since 1879.—E. H. Bradford and James Warren Sever write that, in view of the study of this large number of cases (90), covering such a long period of time, they think that the following conclusions may be stated, namely: (a) That congenital or acquired muscular torticollis may be cured; (b) that an open incision, with complete division of the two heads of origin of the sternocleidomastoid muscle, is all that is necessary, except in unusual cases; (c) that the horizontal incision below the clavicle in the line of the skin cleavage is the best to use, in that it gives adequate room and also gives the best cosmetic results; (d) the plaster-of-Paris is the easiest applied, holds the head in the corrected position, and allows ambulatory treatment, and is, therefore, the best immediate dressing; (e) that the plaster cuirass should be worn not longer than two months; (f) that the Buckminster-Brown brace, Thomas collar, or wire collar should be worn for an average of four months following the removal of the cuirass; (g) that it is best to operate on cases between the ages of two and twelve years, to insure a good result and prevent permanent bony deformity of the face and head.

New York Medical Journal, August 24, 1907.

The Questionable Influence of So-called Diathetic Conditions in Diseases of Throat and Nose in Children.—Charles Gilmore Kerley devotes his attention to enlargement of the tonsils and the presence of adenoids in the nasopharyngeal vault, and records the following observations: (1) The frequency with which these conditions are seen. (2) The distribution of the disorder geographically. The patients are found in large cities, small cities, country villages, in the open country, practically an equal number of children being affected in proportion of the population, regardless of their residence. (3) The distribution of the disorder socially. Hypertrophied tonsils and adenoids are found among all classes, among the very poor and the very rich, and those occupying intermediate positions; among those who live well, and those who live wretchedly. (4) The distribution of the condition among different physical types. The strong and robust, the weakly and those occupying intermediate positions in development and resistance show the growths with practical equal frequency. He believes that the three factors, the sucking habit, the free use of cane sugar, inducing colds, and the tendency to lymphoid tissue involvement, a condition peculiar to all children, contribute largely to the production of adenoids.

The Two Forms of Gastroduodenal Dilatation.—Byron Robinson concludes as follows: In general gastroenterostomy, a grave and unphysiological operation is performed with excessive frequency for unjustifiable causes and nonacceptable clinical data. Gastroenterostomy damages the physiology of digestion, and causes remote troubles. The motor, sensory, absorptive, and secretive functions of the gastrium (as well as those of the duodenum) are disordered. Gastroenterostomy excludes from dietetic circulation unnecessary segments and excessive lengths of the gastroenteron,

which will remotely interfere with nutrition. In gastroenterostomy the prevention of rapid evacuation of the stomach conveys immediately to the jejunum acid foods nonneutralized by the biliary and pancreatic fluids. Also the hydrochloric acid in the duodenum, which stimulates and enhances biliary and pancreatic secretions, is diminished or absent. Gastroenterostomy does not correspond with the clinical data, which in general points to a clamping of the duodenum by the mesenteric vessels, and, if necessary, should be relieved by a limited and definitely localized operation—duodenojejunostomy. Gastroenterostomy may be a justifiable operation in a limited field to-day, but to-morrow it will occupy a still more limited field, with established, recognizable, clinical data.

Absence and Marked Diminution of the Hydrochloric Acid of the Gastric Contents in Cancer Involving Organs Other than the Stomach.—Julius Friedenwald and L. J. Rosenthal examined the acidity of the gastric contents of twenty-nine patients. Nine had cancer of the breast, five of the uterus, seven of the rectum, two of the tongue, four of the face, one of the intestines, and one of the pancreas. In conclusion, they call attention to the fact that Moore has already pointed out—that in doubtful cases of cancer, no matter where the situation of the growth may be, the absence or diminution of the hydrochloric acid of the gastric secretion may at times be a valuable aid in diagnosis. In nineteen of the twenty-nine cases examined there was either an entire absence or diminution of free hydrochloric acid.

Blood Pressure Studies in Typhoid Fever.—Joseph H. Barach offers the following conclusions: 1. It has been shown that the blood pressure falls from the normal after the patient has taken to bed, stays down until convalescence is established, and then returns toward the normal. 2. That typhoid fever is a disease with a blood pressure below 100 (accepting at present the Stanton instrument as a standard). 3. That the blood pressure is governed by factors of its own, and bears no constant relation to pulse rate or temperature. 4. That in diagnosis, blood pressure studies may be of value in differentiating this disease from others, after we know the behavior of other diseases in this respect. In the diagnosis of the complications it has value. 5. That in prognosis the blood pressure chart is of value; a steadily falling pressure means grave danger; so long as the blood pressure keeps up at a reasonable level, we may feel that there is reserve power to work with. 6. That in the treatment of the disease, study of blood pressure will probably be found of the greatest value. It may teach us that the way to combat circulatory failure in typhoid fever is to increase peripheral resistance; or, when to direct our efforts at the heart, and when at the blood-vessels—when it is well to increase, and when it is well to diminish the amount of fluid in the vessels.

Journal of the American Medical Association, August 31, 1907.

Urine Formation.—T. Sollmann summarizes his conclusions as follows: 1. The modifications of Nussbaum's experiment (ligation of the renal artery to exclude the glomeruli from the circulation) prove that in the frog all the normal urinary constituents can be excreted vicariously by either glomeruli or tubules, but the elimination of water, and probably of most other ordinary constituents, occurs normally only by the glomeruli. Certain pigments, on the other hand, are excreted exclusively by the tubercles. It is probable, though not proved, that similar conditions exist in mammals. There is no conclusive evidence that urea is secreted differently from the salts. 2. As stated, the tubular epithelium can secrete all the urinary constituents in the frog. It is highly probable that it secretes pigments in mammals. It is proved that it secretes sugar under the influence of phloridzin, and doubtless it can secrete other substances, but there is no definite evidence that in health it secretes any of the normal constituents. Reabsorption under normal conditions is neither proved nor disproved; its acceptance, however, explains many phenomena. If it occurs it must be selective. 3. Filtration through the glomeruli is physically possible, as it occurs in dead kidneys. The effects, moreover, of saline diuretics correspond closely in both living and dead kidneys, indicating that filtration is an important factor in urine formation, though there is no direct proof. Filtration, however, cannot explain the composition of the urine. 4. It is probable, though not proved, that glomerular urine may, at times, have a much lower concentration than the plasma. The formation of such a fluid would probably require more than the ordinary filtration pressure—in other words, would be a secretory process. 5. It is probable also, though not proved, that the urine ordinarily becomes more concentrated as it passes through the tubules. In any case, the formation of a urine of greater concentration than the plasma requires an unknown force—whether secretory or absorbing—which must be classed as vital. 6. There is no satisfactory explanation of the adaptation of the urine to the needs of the body, none of the proposed theories resting on conclusive proof. 7. There is no binding evidence as to the mechanism of any of the diuretics, but it is highly probable that salts act mainly physically and mainly on the glomeruli, and that phloridzin acts on the tubules. The diuretic action of water, urea and caffein is even more obscure.

Treatment of Acne and Chronic Eczema.—R. H. Boggs reports his experience of the *x*-ray treatment of acne and eczema. He uses the rays in mild cases of acne, after a faithful trial of local and constitutional measures. In pustular and indurated acne he asserts that time is usually lost by waiting. Medication will remove comedones and produce desquamation, but it has little effect on the overactive sebaceous glands as has the *x*-ray; in pustular acne the rays seem to have a fourth action on the staphylococci by rendering the soil inert. Care must be taken to avoid undesirable results, and Boggs has been in the habit of using a very low vacuum tube with the anode at eight inches from the skin, one and a half milliamperes of current and from five to ten minutes' exposure, according to the condition of the patient. He keeps this up for nine treatments; by that time he is usually able to determine how much more will be required, and what variations of the treatment are needed. Acne rosacea, while more resistant, has yielded the best results when glandular inflammation predominates. A majority of cases of eczema require only local treatment and the rays are probably the most efficient form. They are not indicated in the acute forms and are most effective in the squamous type. In papular eczema more intense radiation is required to relieve the pruritus and relapses are more frequent. In chronic squamous eczema the skin is in poor condition, nutrition and vitality are depressed, and more than a mild dosage is liable to result in a severe dermatitis. He uses a low tube, ten inches from the surfaces, with one and a half milliamperes current, provided that the patient is in good physical condition; a safe rule is to start with ten minutes' exposure three times a week. He finds eight or ten such treatments will clear up many cases of squamous eczema, but a second trial may sometimes be required.

Excision of Carcinoma of the Breast.—M. F. Porter describes his technique in the operation for mammary cancer, and points out its apparent advantages. The superficial incision varies to suit the case, but the one he finds most generally useful begins at the humeral insertion of the pectoralis major and follows its lower border till the breast is reached, then surrounding the gland in a somewhat elliptical fashion so that when coapted the line of coaptation will occupy about the position of the lower border of the normal pectoral muscle, save that it extends more downward and inward. All the pectoralis major, except the clavicular portion, and the abdominal portion when present, should be removed, together with the whole of the pectoralis minor, the axillary fat and glands, and the breast with its coverings. Complete closure of the wound is important and can generally be secured, and drainage dispensed with, if due attention is given to making the right incision, the securing of hemostasis and the use of tension sutures. Venous stasis in the arm and lack of motion in the shoulder, as postoperative results, can usually be avoided by guarding against infection and keeping the wound surfaces in close apposition until healing is complete. For this, he states that the best means is the use of a few buried sutures in the apex of the axilla and a properly adjusted compressive dressing kept in place by adhesive plaster. Porter specially advises against continuing the superficial incision into the axilla on account of the greater risk of infection here and the interference with arm motion by the resulting scar. He claims for his method, which is given in full detail and illustrated, that it is simpler and easier than other methods, more comfortable to the patient, and gives a more rapid recovery and greater certainty of good results.

Plastic Radiography.—W. G. Stern and E. Rosenberg describe a provisional modification of the method or-

iginated by Bela Alexander of producing *x*-ray photographs giving relief effects with shadows and high lights. They use two plates: First, a double-coated, specially prepared plate with a double exposure to two tubes, first a soft, then a hard tube. The first exposure is longest, and after the development a positive plate is made; the two are fastened back to back and prints made from the positive, on bromide paper with artificial light furnishing parallel rays striking the plate at an oblique angle. They do not attempt to explain how the plastic effect is produced by this procedure.

Frontal Sinus Operation.—R. H. Good describes an operation as performed by him for frontal sinusitis by the intranasal route. The instruments used are figured; they are comparatively inexpensive, including two frontal sinus rasps, two tapering curved chisels and three brass protectors capable of being bent into various shapes on the flat, but not sideways. They are used when operating with the chisels, which are tapering as well as blunt on the edges, so that if the edge should strike a bony surface it would glide off instead of penetrating. The rasps are made on the principle of the old-fashioned coarse horseshoe rasp, slightly curved to fit into the frontal sinus and with the teeth on the longitudinally concave surface, pointing toward the handle. The different steps of the operation are described in detail. Good thinks his rasp is preferable to the mechanical burr, being cheaper and more under control, therefore less dangerous, and that a large proportion of frontal sinusitis cases can be cured by his method, which can be safely used instead of the external disfiguring operation.

The Quality of Public Water Supplies.—W. S. Johnson, as an engineer, accustomed to exact methods, says it is exasperating to find so much uncertainty existing as to the true relations of defective water supply and disease. Fortunately, however, the engineer, in dealing with water-supply problems, is working for something beyond the public health, namely, public comfort. The demand now is, at least in many parts of the country, for a water that will not merely not produce typhoid, but water from undefiled sources, not too hard, or objectionable in appearance, taste, or odor. The only source in Nature of such a supply is the ground water, and a good ground water is clear, colorless, odorless, and practically free from any organic contamination. Any community, he says, which is favored with large areas of sandy or gravelly subsoil from which water can be obtained has little excuse for a poor supply. This does not mean artesian wells, but shallow wells from thirty to fifty feet deep. When the sandy or gravelly area is not extensive, much can be done by infiltration from neighboring surfaces if the wells or filter galleries are properly placed. The water-supply problem could often be greatly simplified if the proper utilization of ground water were understood. When ground waters are unavailable, the most satisfactory substitute is a filtered surface water. Nevertheless, Johnson deprecates the tendency to depend too exclusively on filtration, as liable to lead to dangerous conditions, if anything should happen to prevent the proper working of the filtering apparatus. Surface waters can be greatly improved by storage under suitable conditions and for sufficient time, as is shown by the experience of large cities like Boston and New York, where typhoid epidemics attributable to the water supply do not occur, although these cities draw their water from reservoirs, the feeders of which are known to be polluted. The weak points of such supplies are the possibility of contamination near the outlets of the reservoirs and bad taste due to the growth of organisms. Running streams are the least desirable sources of water supply; it is practically impossible to insure them against contamination. Experience is teaching us that the nearer we can get to Nature's methods of disposal of sewage or purification of water, the better.

The Lancet, August 17, 1907.

Notes on a Case of Carcinoma of Both Ovaries.—M. P. Kerrawalla reports the case of a woman, forty-seven years old, married, who had had three children, the last twenty years ago. She had no miscarriages. Her mother died of cancer of both breasts when fifty-two years old, as also had her mother's two sisters. Her own sister was healthy, as also was her daughter. Three weeks before admission to the hospital she first noticed an abdominal swelling, which was only up to the level of the symphysis pubis. In about ten days more the swelling rose up to about two inches from the umbilicus. At operation a large ovarian cyst was discovered and tapped, letting out about forty ounces of what looked like ordinary ovarian fluid. The cyst wall was adherent to the posterior surface of the uterus and the left broad ligament and had to be separated, leaving a raw, oozing surface. The inner surface of the cyst wall showed large warty growths. The pedicle was soft and friable. The uterus felt normal. The right ovary was enlarged to the size of a Tangerine orange and was hard with papillomatous growths on its surface. No secondary deposits were discovered. A fortnight after the operation the cervix and the uterus felt normal and freely movable per vaginam and the patient left the hospital greatly improved. The pathologist reported the growths to be carcinomatous.

On the Continuous Administration of Fluids by the Rectum in the Treatment of Acute General Peritonitis.—B. G. A. Moynihan comes to the conclusion, after a fairly large experience, that there are few recent therapeutic measures which are in value equal to the continuous administration of fluids by the rectum in the treatment of general peritonitis. He has treated nineteen consecutive cases of acute general peritonitis due to appendicitis, with two deaths, and the recovery of several of these patients is, he believes, largely, if not solely, due to the continuous administration by the rectum of saline solution over a period of two to four days after the operation. In two recent cases of partial gastrectomy and one case of complete gastrectomy the recovery of the patients was undoubtedly helped by this abundant supply of fluid to them. This method he considers safe; it is easily borne by the patient; it effects a very remarkable change in the appearance and in the prospects of recovery after serious abdominal operations; the quantities which can be retained by a patient without discomfort do not throw a strain upon the kidneys which they find difficult to bear.

A Note on Hypopharyngoscopy.—Harold S. Barwell reports a case of extensive involvement of the pharynx in which operation was contraindicated, and in which Van Eicken's method was of great use in showing at once the extent of the pharyngeal involvement and therefore proving the case to be inoperable. This new method, devised by van Eicken, for the examination of the hypopharynx, or that part of the pharynx which lies below the aperture of the larynx, was described in *The Lancet* of May 25, 1907, by Dr. P. Tetens Hald of Copenhagen.

Tuberculosis Among School Children.—T. N. Kelynack says that it is estimated that in the United Kingdom more than one-third of all deaths between fifteen and thirty-five years of age are due to pulmonary tuberculosis. Of the 1,200,000 new lives added annually to the population, one-fourth to one-third are born in homes where conditions exist strongly predisposing to tuberculosis. Taking all cases on which post-mortem examinations are made under fifteen years of age, Harbitz of Christiania finds tuberculous lesions in 42.5 per cent.; Hamburger and Sluka, in Vienna, 40 per cent.; and Comby, in Paris, 38.5 per cent. According to statistics at present available for England and Scotland tuberculosis is said to be present in from less than 0.5 per cent. to over 6.0 per cent. of school-going children. Tuberculosis, more particularly of the lungs, exists among many teachers. In considering the subject of tuberculosis among children of school age, it is very necessary to break away from all restricting conceptions and to view the school and its scholars from the broadest hygienic standpoint. He believes that most of the cases occurring among children of all ages are home-born and home-grown. School sanatoriums are badly needed. Tuberculous children should not be sent to a sanatorium with consumptive adults. Much good would come from forming an International Association for the Study, Prevention and Treatment of Tuberculosis Among Children.

British Medical Journal, August 17, 1907.

The Prodromal Period of Some of the Acute Infectious Diseases.—E. W. Goodall deals chiefly with cases in which the initial symptoms are either unusual or not sufficiently emphasized in textbooks. The prodromal stage is that which intervenes between the first symptoms of illness and the rash or some other characteristic sign. In the majority of the cases of scarlet fever the prodromal period is short. Usually the rash comes out within forty-eight hours of the onset, and very often it is discovered as soon as any other symptom; occasionally it is delayed until the third or fourth day, and even longer. As a rule, when the appearance of the rash is delayed, the case is one in which the throat symptoms are marked; these latter cases are frequently diagnosed as diphtheria. Vomiting is a very common early symptom of scarlet fever. Prodromal rashes are extremely rare, if they ever occur. The only sign of an attack of scarlet fever may be a punctate eruption. Diphtheria is so insidious in its onset that it is

often well advanced before it betrays any sign of its presence. Croup may be the first sign of diphtheria. In rubella the rash appears synchronously with any other symptom. Prodromal rashes in measles are common, the most frequent being a punctate erythema; these cases are often mistaken for scarlet fever. The next most frequent rash in measles is an erythema consisting of small discrete papules, with blotches and irregular patches of confluent papules. Another prodromal rash is urticaria, which is usually universal. One may also meet with an ill-defined erythematous mottling, especially noticeable on the trunk. Remissions are fairly frequent and may last from twelve hours to four days, when the constitutional symptoms recur and the rash comes out. An early laryngitis is by no means uncommon and usually passes off when the rash comes out. Koplik's spots usually come out early, on the first or second day; sparse at first, they increase in number daily till the rash appears, when they rapidly vanish. The spots are pathognomonic, and it is their presence which enables one confidently to diagnose the disease in cases where the prodromal rash, the remissions, or the laryngitis are doing their best to lead us astray. Usually there is no prodromal period in varicella, and the eruption is the first or among the first signs. Typhoid fever is the most protean in its mode of onset of all the acute infectious diseases.

Bottle-makers' Cataract.—William Robinson gives summaries of cases of cataract observed in three factories in the Sunderland District, where 400 men are employed. The number of men known to have cataract is 40, 37 of which occurred in bottle finishers. These figures he believes to be unparalleled in any other trade. Sight began to fail in the large number of the cases between the ages of 41 and 50. Both eyes are almost always affected. He also gives statistics obtained from the glass bottle makers of the Yorkshire United-Trade Protection Society, whose members number 2,623; but of these only 1,341 were employed in December last. Of 114 superannuated members 37, or 32.4 per cent., had cataract. The average age of disablement was 57.3 years. In addition to the 37 with cataract, 11 others had eye affections, making a total with eye disease of 48 men, or 42 per cent. of the whole family. He gives statements that lend support to the belief that the excessive heat of the gas furnaces is the cause of the disease.

Acquired Syphilis in an Infant, with Transmission to Mother.—J. A. Nixon reports a case in which there seems to be no doubt that the mother had acquired syphilis, and that the breast had been the site of the chancre, which was derived from a similar and earlier lesion on the child's lip. The origin of the latter remains unexplained.

Berliner klinische Wochenschrift, August 12, 1907.

Concerning the Specific Action of Amboceptors.—Eysbroek endeavors to show that the claim of several investigators, to be able to distinguish between various species of bacteria of the same class by means of the method of fixation of complement, is wrong. He used an antistreptococcus serum derived from a horse which had been injected with various kinds of streptococci, and found that the serum (amboceptor) was not only active for the five different kinds of streptococci which were used to immunize the horse, but that fixation of complement also occurred with various other pathogenic streptococci. The latter included streptococci from angina, scarlatina, cholecystitis, and puerperal patients, both those which had been successfully and unsuccessfully treated with the serum. The serum was even active to meningococci and pneumococci. He, therefore, concludes that the method of fixation of complement cannot be applied to identify various bacteria and that amboceptors are not absolutely specific.

Münchener medizinische Wochenschrift, August 6, 1907.

Results of Alcohol Injections in Neuritis and Neuralgia.—Fischler tried this method of treatment in obstinate sciatica and trigeminal cases. One to one and a half c.c. of a 70 per cent. solution of alcohol was injected into the nerve at intervals of two to eight days. In sciatica cases the hypodermic needle was inserted and the nerve felt for, at the point of greatest local tenderness or where the nerve emerged from the pelvis, between greater trochanter and ischium, its finding being signalized by a severe pain down the legs. After the nerve was found the needle was slightly withdrawn, to make certain it was not in a vessel; the fluid was then injected slowly and the patient carefully watched. The latter at first experienced a severe pain down the entire leg, or a burning or tingling sensation, or a feeling of numbness, which disappeared in a few moments or hours, and with it the sciatica pain as well. Of twelve cases, four were absolutely cured, four unimproved, and the remainder partly improved. The fact that they were not all cured he attributes to insufficient treatment, and treatment not properly carried out. Six cases of supra- and infraorbital neuralgia were entirely cured. In the last sciatica patient subjected to treatment, a paralysis of the perineal region set in after the fifth injection, which was made with the perineal nerve, it took one year to recover. This case and three of Erb's, one of facial and two of tibial toxic neuritis, caused by alcohol injections, induced Fischler to abandon this mode of treatment in diseases of nerves containing motor fibers, while he continues it in diseases of nerves containing only sensory fibers. The degeneration which the alcohol sometimes causes of the nerve into which it is injected makes its use ideal in sensory nerve affections. Fischler does not advise against alcohol injections, but warns against their dangers which, after further experience in regard to method and indication, may possibly be avoided.

Generalized Vaccina.—Danziger reports a small epidemic of this disease. A six months' old boy was admitted to the children's ward of a hospital with the diagnosis of generalized vaccina; the infant had never been vaccinated, but fifteen days previous to its admission its sister had been vaccinated. Eight to twelve days after his admission, five out of six non-vaccinated children in the ward—three of whom were being treated for eczema, one for congenital syphilis, and one for impetigo contagiosum—had also developed generalized vaccina, while none of the vaccinated children contracted the disease. Danziger believes that it is still a matter of discussion whether this disease is a result of accidental or autoinoculation, or whether it is a general infection through the digestive, circulatory, or respiratory system. In this epidemic he thinks the balance of evidence is in favor of a generalization from within, for all but one patient had a cough at the onset which in his mind speaks for an infection through the respiratory tract. The fact that the first patient had no skin lesion speaks against the inoculation theory, and yet he holds that children with a skin disease are more prone to become infected. As regards the effect of the generalized vaccina on the preexisting skin lesion, the epidemic proves nothing, as the skin condition got worse in two patients and healed readily in two others. The prognosis he holds to be good, as the syphilitic child only, died. In conclusion he says that generalized vaccina is contagious, can occur in epidemics, and that the patient afflicted with it should be isolated from non-vaccinated children, especially if these have an eczema or other skin disease. The infrequency of the disease he attributes to the fact that as a rule eczematous children are not vaccinated.

A Case of Congenital Syphilis of the Small Intestine and the Etiological Significance of Spirochæta Pallida.—Fränkel relates the history of a case of congenital syphilis of the small intestine, describing in detail the relation of the *Spirochæta pallida* to the intestinal lesion. The patient was a premature child, forty-seven centimeters long, which died of acute peritonitis when five days old. At autopsy several coils of the upper portion of the ileum were found closely bound together by adhesions; these and other loops of small intestine were covered with pus, while about 100 c.c. of a reddish cloudy fluid was found free in the peritoneal cavity. On opening the gut it was found to contain numerous ulcers, extending through the entire thickness of the wall up to the serosa, as well as circumscribed areas which were raised above the level of the mucous membrane. The duodenum, jejunum, lower portion of ileum, and large intestine were found to be normal. The firm adhesions between the loops of ileum were more than five days old, so that this chronic peritonitis began during the child's intrauterine life, while the acute purulent peritonitis was recent, both having as the underlying cause the pathological changes in the intestinal wall. Spleen, suprarenals, pancreas, lungs, heart, and kidneys were normal, while the liver contained small adenomata and the ribs were the seat of a syphilitic osteochondritis, which was, however, detected only on microscopical examination. On the strength of the raised areas on the inner surface of the intestine and the osteochondritis, he made the diagnosis of syphilis, and then tried to substantiate it by staining for spirochete. The latter were found in the borders of the raised areas and ulcers, as well as in the immediately surrounding tissue; while they were absent

even a short distance from the diseased tissue, and also in the necrotic floors of the ulcers. The vast majority of spirochete surrounded the crypts of Lieberkuhn and the vessels of the submucosa, a few only being present in the muscularis and upper layers of the mucosa; an occasional one was seen in the lumen of the glands and between their lining epithelium. From his findings he feels justified in stating that the so-called *Spirochæta pallida* is of parasitic origin, and is not a neurofibril, as has been claimed by some, for neurofibrils are not found in such large quantities around Lieberkuhn's glands or inside of the latter. Furthermore, the fact that the child lived five days and was not macerated speaks against the argument of those who claim that maceration only is necessary to get bodies like the spirochete when the tissue is stained with the silver method. Histologically the ulcers consisted of serosa, subserosa, and small portions of muscularis; the mucosa and submucosa were entirely missing. The raised areas were caused by a swollen submucosa, muscularis, and subserosa. While the mucosa was destroyed, in the center of the swollen portion necrosis had begun. He points out that it was a simple process quite different from the one usually found in syphilis, there having been no preceding vessel changes which caused eschemia with following necrosis. The anatomical process which led to the formation of an ulcer shows nothing characteristic for syphilis; of so much greater importance therefore was the finding of the spirochete.

Deutsche medizinische Wochenschrift, August 8, 1907.

Purulent Inflammation of the Labyrinth.—Heine contributes an account of this disease, confining himself, however, to such inflammation as is caused by middle ear disease, as he considers this kind of the greatest practical importance. He says the pus usually enters the labyrinth through points of least resistance, *i.e.* through the fenestra ovalis, through the fenestra rotunda, and through the attic into the ampulla of the horizontal semicircular canal, exceptionally the pus breaks into the vertical semicircular canal and into the tip of the cochlea. The disease may be circumscribed or diffuse; if the latter, the canal for the facial nerve is usually involved and the carotid may become eroded. The disease may heal spontaneously, when the sequestra are expelled and connective tissue or new bone takes their place, or it may go on to involve the brain; when it advances by way of the equeducts, the cochlea, or along the arachnoid coverings of the nerves or breaks directly through the wall of the labyrinth into the brain, thus causing a localized abscess or meningitis. Any insult to the labyrinth may cause dizziness, nausea, vomiting, ringing in the ears, disturbances of hearing, and nystagmus, but their presence does not necessarily mean involvement of the labyrinth, though if middle ear disease exists, dizziness and nystagmus usually point to labyrinth trouble. The cases which are difficult to diagnose are those with no symptoms, no signs during operations, but which afterward suddenly develop meningitis and show total destruction of the labyrinth at autopsy. The labyrinth contains two sets of nerve endings, the one concerned with hearing being situated in the cochlea, the other concerned with equilibrium being situated in the vestibule. The symptoms depend upon which nerve endings are affected, and whether the latter are just irritated by the diseased process or totally destroyed by it. An irritation of the nerve endings manifests itself by subjective noises when confined to the cochlea, and by nystagmus and dizziness when confined to the vestibule. On the other hand, if destruction of the nerve endings takes place, deafness sets in when the cochlea is involved, but when the vestibule nerve endings are destroyed the condition is not so easily diagnosed. Heine goes on to describe Stein's and Wanner's test for the "equilibrium sense," but found by experience that the former is complex and dangerous, while the latter is unreliable. He believes that the method of Barany is simple and usually reliable; it consists in throwing water below body temperature into the external auditory canal, when in individuals whose vestibule is healthy a rotary nystagmus takes place towards the opposite side, while if water warmer than body temperature is used the nystagmus will take place towards the injected side. This is true whether the drum membrane be intact or not and the phenomenon does not take place in persons whose vestibular apparatus is destroyed. When nystagmus, dizziness, nausea, and vomiting are caused by pressure due to a middle ear disease with pus, a paracentesis will relieve the condition; if due to the pressure of a brain abscess the differential diagnosis is more difficult; if caused by abscess the nystagmus may first be directed to the healthy side, but later is turned towards the diseased side and is always more marked than in labyrinth disease. Subjective noises, too, may be caused by conditions other than an irritated nerve apparatus in the cochlea; but if they occur suddenly in connection with other symptoms during the course of middle ear disease, they point toward involvement of the cochlea. No matter what the symptoms, the findings during operation are his guides as to how the labyrinth should be treated. If the symptoms before operation point to destruction of the vestibular apparatus and during operation he finds a labyrinth fistula or a large crater-like defect in the ampulla of the horizontal semicircular canal or pus coming out of the vestibule, the latter is cleaned out. Whether or not the cochlea is to be opened depends on whether deafness was present before operation or whether it looks affected during operation. With or without symptoms due to irritation before operation, he cleans out the labyrinth, if the above changes are found during operation. On the other hand, even if nystagmus and dizziness existed before operation, and during the latter a small defect is noticed in the horizontal semicircular canal, he leaves this alone, as such defects usually heal spontaneously, and any disturbance during operation might only change a circumscribed condition into a diffuse purulent inflammation of the labyrinth. If, however, labyrinth symptoms persist, become more intense, or only appear after operation, the labyrinth must be cleaned out, even though the portal of infection of the labyrinth cannot be seen.

Etiology of Trachoma.—Halberstaedter and Prowazek found peculiar bodies enclosed in the conjunctival epithelium of trachoma patients, which they believe play a rôle in the etiology of the disease. They stained smears taken from the conjunctiva of such patients according to the Giemsa method, and found round and oval dark blue and violet bodies near the nucleus of the epithelial cells, the latter appearing normal in every other respect. These masses were not quite homogenous and contained small bodies staining red. Later the blue masses were found to break up, while the red bodies had greatly increased in number; in still later stages the blue masses separated into small islands, which went to the periphery of the entire mass, now chiefly consisting of red bodies. They hold that the blue masses are reaction products of the cells and that the small red bodies are microorganisms, for (1) they were always present in the same way; (2) they multiplied; (3) when epithelial cells containing them were placed into the eyes of an orang-outang they caused trachoma and were found there in great numbers. These two observers furthermore believe that trachoma primarily affects the conjunctival epithelium, and that the swelling of follicles is only secondary, as these bodies are found in the epithelial cells only, and as follicles are also found in chronic blenorrhea, in infections with the diplococcus and pneumococcus, etc. During their experiments they made control tests and never found any such red bodies in the conjunctiva of healthy individuals nor in eyes afflicted with keratitis, carcinoma, blenorrhea, etc.

French and Italian Journals.

Independence of Cerebral Development in Hypertrophic Infants.—G. Variot points out the fact that in healthy children the brain develops according to fixed rules of growth. At the age of two, while the child is not nearly arrived at its final growth, the brain development has nearly reached its adult form. This rapid growth accounts for the frequent location of the bacillus of tuberculosis in the brain. In hypertrophic children the brain growth corresponds rather to the age than to the size of the child, and in cases that are much stunted in size and weight it is found by weighing the brain and measuring the skull after death that the brain development is far in advance of that of the rest of the body. It is also to be seen by the expression of the infant's face that it understands and recognizes far more than children of its size ordinarily do. This relative independence of cerebral development accounts for the frequency of psychomotor disturbances in hypertrophic children.—*Annales de Médecine et de Chirurgie Infantiles*, April 1, 1907.

Goiter in the New-Born.—Planchu and Richard say that goiter may be congenital and hereditary in new-born infants, and is a very grave disease. The symptoms are cyanosis, dyspnea from compression of the trachea, cough, and difficulty in deglutition from pressure on the esophagus. The dyspnea may be so severe as to require inversion of the child to relieve it, or tracheotomy. The tumor extends across the neck, or forms two pyramids with the apices upward and backward. There are three forms. The parenchymatous is rare, there being only one autopsy recorded. The vascular is most common. It consists of much dilated veins which form large sinuses, with a small amount of tissue surrounding them. This form is generally gradually absorbed. The cystic also occur. Treatment in severe forms is operative, exothyropexy being preferred. Thyroidectomy is too severe an operation to perform in the infant.—*Gazette des Hôpitaux*, May 11, 1907.

Book Reviews.

THE NURSLING. The Feeding and Hygiene of Premature and Full-Term Infants. By PIERRE BUDIN, Professor of Obstetrics, University of Paris, etc. Authorized Translation by WILLIAM MALONEY, M.B., Ch.B., Fellow of The Obstetrical Society of Edinburgh, etc. With an Introduction by Sir A. R. SIMPSON, M.D., LL.D., etc. London: The Caxton Publishing Co., 1907.

PROF. BUDIN is perhaps the man in France best qualified to discuss a subject which has been recognized in his country to be of such extreme importance that it has received recognition by the national government. The birth rate of France has been steadily decreasing, and the means taken to overcome this calamity has been accorded governmental recognition. The question has been studied from two standpoints, that with regard to the conditions which foster and favor antenatal life and that which is concerned with the methods which preserve and promote the growth of the infant. In this volume Prof. Budin explains in ten lectures the methods which he has found successful in nourishing the young child, whether normal or feeble or premature. Prof. Budin's efforts in organizing the "consultations de nourissons" in various French cities have been the means of reducing the infant mortality of that country to a marked degree. The author seems to favor pasteurized milk as the only rational substitute for breast feeding, and considers it superior to refrigerated milk. He believes that with few exceptions undiluted milk may be given to all infants, and he uses diluents, such as water or gruels, only in certain cases. Pasteurization is claimed to render the milk fit for infant digestion without the addition of other substances. This statement will be disputed in this country without doubt, as it is a view but rarely held here. Aside from such a difference of opinion, however, the book will certainly meet with a favorable reception for its other interesting qualities.

THE ELEMENTS OF THE SCIENCE OF NUTRITION. By GRAHAM LUSK, Ph.D., M.A., F.R.S. (Edin.), Professor of Physiology at the University and Bellevue Hospital Medical College, New York City. Illustrated. Philadelphia and London: W. B. Saunders Company, 1906.

IN presenting this volume to medical readers Professor Lusk has done much to remedy the deficiency of American textbook literature on the subject. The treatment of the so-called diseases of metabolism has become so largely a matter of diet that their management, according to modern views, absolutely requires thorough familiarity with the principles of nutrition; but there is hardly a medical or surgical condition of any sort that cannot be better understood or treated by one who has devoted thought and study to this subject. The ability to think of diets in terms of calories is most useful to the practitioner and is not very difficult of acquirement, and the present volume is well adapted to convince the most sceptical of the practical importance of such knowledge. The first 160 pages comprise eight chapters on the general principles of metabolism investigations and the subject of nutrition as influenced by starvation, temperature, mechanical work, etc. Then follow two chapters on the normal diet and on the food requirements during the period of growth, and the last third of the volume is made up of a series of discussions of what might be termed the pathology of metabolism. Anemia, gout, diabetes, fever, myxedema, etc., are taken up and their relation to the processes of nutrition is set forth. The book closes with an appendix consisting of tables relating to food values and equivalents. The author's facile style renders the perusal of the volume doubly interesting, and the book may be commended to the attention of all medical readers.

HYGIENE OF NERVES AND MIND IN HEALTH AND DISEASE. By AUGUST FOREL, M.D., Formerly Professor of Psychiatry in the University of Zurich. Authorized Translation from the Second German Edition. By HERBERT AUSTIN AIKINS, Ph.D., Professor in Western Reserve University. New York and London: G. P. Putnam's Sons, 1907.

THE author's conception of popular hygiene is that it enables an intelligent layman with a fair education to govern his life in such a way as to avoid diseases and abnormalities as far as possible for himself, his fellow men, and his offspring, and to promote the health and strength of them all in every respect. Further on he lays down as a fundamental proposition that "Public, or rather social, hygiene, should everywhere be superior to individual hygiene when there is a conflict between them; and there are many conflicts." Hence there can and should be no conflict between hygiene and ethics. The book is divided into three parts: the first dealing with the mind, brain, and nerves in their normal condition; the second, with the pathology of the nervous life; and the third, with the hygiene of the mental life and of the nervous system. The book is a good one and will appeal not only to the practitioner, but also to many of his patients. The third part of the book, particularly, contains much information that the laity might absorb with profit to themselves and to their neighbors.

A LABORATORY MANUAL OF INVERTEBRATE ZOOLOGY. By GILMAN A. DREW, Ph.D., Professor of Biology at the University of Maine; in charge of Zoological Instruction at the Marine Biological Laboratory, Woods Holl, Massachusetts. With the Aid of Members of the Zoological Staff of Instructors of the Marine Biological Laboratory, Woods Holl, Mass. Philadelphia and London: W. B. Saunders Company, 1907.

THIS laboratory manual is based on the directions prepared by members of the staff of instructors to meet the needs of the class in general zoology at the Marine Biological Laboratory of Woods Holl. The ground is covered very thoroughly, and the volume contains "directions" concerning quite a large number of accessible types of all the chief groups of animals. The book has stood the test of six years' practical work, and so can be confidently recommended to teachers and students of biology.

A TEXTBOOK OF EMBRYOLOGY for Students of Medicine. By JOHN CLEMENT HEISLER, M.D., Professor of Anatomy in the Medico-Chirurgical College, Philadelphia. With 212 illustrations, 32 of them in colors. Third Edition, Thoroughly Revised. Philadelphia and London: W. B. Saunders Company, 1907.

IN this new edition many of the sections have been either rewritten, altered, or enlarged, so as to bring the book up to the level of recent investigations in the field of embryology. These changes are chiefly noticeable in the paragraphs dealing with the ovum, the spermatozoon, the blastodermic vesicle, the amnion, the vascular system, the pancreas, the spleen, the larynx, the thyroid, the parathyroid, the thymus, the kidney, the suprarenals, the spinal cord, the vitreous, the muscular system, and the vertebral column. The present volume makes an interesting and connected story of the development of the human body; at the same time each chapter is fairly complete in itself, thus facilitating reference to any special topic.

A TEXTBOOK OF MATERIA MEDICA FOR NURSES, Including Therapeutics and Toxicology. By GEORGE P. PAUL, M.D., Attending Physician and Adjunct Radiographer to the Samaritan Hospital at Troy, N. Y.; Author of "Nursing in the Acute Infectious Fevers." Philadelphia and London: W. B. Saunders Company, 1907.

THE subject matter of this book is arranged in six parts. Part I contains general considerations, definitions, preparations, actions, administration, and classification of drugs. Part II deals with general materia medica, and constitutes the main part of the volume. The drugs are here arranged alphabetically, and are discussed under the various headings: derivation, synonyms, constituents, dosage, preparations, physiological action, therapeutic indications, administration, pre-toxic signs, and toxicology. Parts III and IV mention drugs of minor importance and newer remedies. Part V is on practical therapeutics and discusses: hydrotherapy, hypodermic medication, antiseptics, and disinfectants, disinfection, topical medication, application of heat, rectal alimentation and medication, antitoxins and serums. Part VI contains a list of synonyms, tables of weights and measures, and strength of drug preparations. This volume will be of real help to nurses; the material is well selected and well arranged; and the book is as readable as it is useful.

PSYCHOLOGY APPLIED TO MEDICINE. Introductory Studies by DAVID W. WELLS, M.D., Lecturer on Mental Physiology and Assistant in Ophthalmology, Boston University Medical School; Ophthalmic Surgeon, Massachusetts Homeopathic Hospital, Boston; Oculist, Newton (Mass.) Hospital. Philadelphia: F. A. Davis Company, 1907.

THIS volume is an attempt to bridge over the gap between psychology and medicine. It is written chiefly for two classes of readers: (1) the medical student who has had no previous training in "psychic matters," and (2) lay readers who know little or nothing of medical technicalities. The nine chapters discuss, in order: Reason and Instinct, Habit, Sensation, Experimental Psychology, Hypnotism (History, Phenomena, and Theories), Psychotherapeutics, and the Psychic Element in Medicine; a brief bibliography is appended. The greater part of the book is taken up with hypnotism and mental healing; as a first book on these subjects it can be recommended to those interested.

Society Reports.

AMERICAN THERAPEUTICAL SOCIETY.

Eighth Annual Meeting, Held in Washington, D. C., May 4, 6, and 7, 1907.

(Special Report to the MEDICAL RECORD.)

ROBERT REYBURN OF WASHINGTON, PRESIDENT, IN THE CHAIR.

THE address of welcome was delivered by Hon. Henry B. F. McFarland, President of the Board of Commissioners for the District of Columbia. Dr. Reynold Webb Wilcox, New York, responded for the visiting members.

Fifty Years in the Practice of Medicine.—Dr. ROBERT REYBURN of Washington, D. C., took this as the title of his presidential address. After speaking of his early medical career, he described the methods of treatment used in the period following the year of his graduation, 1856. Vaccination was performed by pulverizing vaccine crusts and inserting the moistened powder into the arm. The antiphlogistic method of treating inflammation was still in vogue—bleeding, blistering, purging. While no one would wish to revive bleeding after the old methods, yet he had seen cases in which prompt venesection had saved life. In eclampsia, threatened apoplexy, and even acute pneumonia he had seen prompt relief afforded in this way. The antiphlogistic method was followed by a reaction, and in 1860 and 1862 stimulants were given in inflammatory conditions. After describing surgical methods in vogue prior to the Civil War, he contrasted the high mortality from gunshot wounds in the Civil War with the low mortality in the Spanish-American war. In the latter the universal use of first-aid by antiseptic dressings did more than anything else to lessen the mortality. Also, the rifles used were more humane, in that they carried a small bullet of high velocity, which penetrated the tissues more readily and caused less shattering than did those of the Civil War. The paper then dealt with personal recollections of President Lincoln and of the scenes following his assassination. The address closed with an account of the assassination, illness, and death of President Garfield, Dr. Reyburn having been one of the physicians in attendance.

Pure Drugs.—Dr. HARVEY W. WILEY of Washington, after referring to the different classes of therapeutic agents, discussed the attempts that had been made to control the purity of drugs used as medicines. Dr. Wiley was unable to say how far the new food and drugs act would be applied to the inspection of drugs. The question was now before the Attorney-General for decision. If he adopted the common principle of construction, inspection by the Treasury Department would continue as before, with an additional inspection as required by the act of June 30, 1906. It was probable that at least 20 per cent. of the drug trade would be affected by the provisions of the new law. He suggested that no one should be allowed to advertise or offer for sale to the public any remedy who had not passed an examination before a medical examining board and received a license to dispense medicines and prescribe for patients in the locality mentioned. Thus the patent medicine trade would be much restricted.

Dr. REYNOLD WEBB WILCOX of New York spoke of the standards set forth in the Pharmacopœia. Seven years ago he was appointed a member of the Revision Committee. The aim of the committee had always been to maintain the necessary efficiency and purity of drugs, without making the standards so high that manufacturers could not come up to them. They were established after careful study and conferences with manufacturers.

Dr. E. H. LONG of Buffalo said that the profession could well rejoice that it had the aid of the Government in the matter of drug control. He commented upon the prevailing neglect of medical schools to furnish adequate instruction in the art of prescribing and the use of reliable and well-known remedies.

Dr. OLIVER T. OSBORNE of New Haven said that now was the time to let the label tell. He related a recent experience at Hartford in an effort to get poison labels on bottles. There was much opposition from pharmacists and others, and finally two strenuous bills were brought before the Legislature. Much to his satisfaction, however, the business men agreed at the preliminary hearing that they preferred the provisions of the new food and drug act. He expressed regret that young physicians in the hospitals were prone to prescribe compounds which were kept upon the shelves, ready-mixed, for the sake of convenience. Thus they soon lost their ability to write their own prescriptions.

Dr. F. E. STEWART of East Orange commended Dr. Wiley's work. The medical profession and the public could not be too grateful for Government aid. He commended Dr. Wiley's suggestion as to license requirement. Dr. Gould had said that any one can practice medicine without a license except a physician or a pharmacist.

Some Criticisms of the United States Pharmacopeia. Dr. REYNOLD WEBB WILCOX of New York answered some of the criticisms that had appeared since the last revision became official, in 1905. 1. "Many agents have been retained that are not in general use, while others much used have been omitted." As a matter of fact, the changes were made only after the committee had consulted manufacturers, wholesale and retail druggists, and the members of the medical profession throughout the land. Every suggestion, no matter how humble its origin, was considered. 2. "More frequent revisions of the pharmacopeia are necessary." A greater frequency would not be possible, because time was needed for definite knowledge of medicinal substances. Active work for nearly five years was required for the present revision, and this represented about the shortest time in which the work could be done. 3. "The time had come when the American Medical Association should take a hand in this work." Dr. Wilcox answered this criticism at some length, calling attention to the make-up of the Revision Committee. The medical profession was represented by twelve out of twenty-six members. The unfortunate showing which the Council on Pharmacy and Chemistry had made also demonstrated the utter unfitness of the American Medical Association to undertake the far more serious work of revising the Pharmacopœia.

L. F. KEBLER of Washington agreed with Dr. Wilcox as to the status of the U. S. Pharmacopœia. He knew of none equal to our own. It unquestionably had faults, but they would be remedied as rapidly as practicable. He expressed regret that Dr. Wilcox had so severely criticised the Council. It had accomplished something; for this it deserved credit.

Dr. S. L. DAWES of Albany referred to the nomenclature used in the Pharmacopeia. The names of remedies were in many instances too long and complex. They could be simplified to good advantage. Students who were taught long and complex names for drugs soon discarded them, after graduation, for simpler terms.

Dr. E. H. LONG of Buffalo said that the Council on Pharmacy and Chemistry of the American Medical Association was young; nevertheless it had done some good.

Dr. OLIVER T. OSBORNE of New Haven said he hardly found his prescription blanks long enough for some of the terms he had to use. He suggested that accent marks be used in the next Pharmacopeia in order to secure uniformity in pronunciation. He commended the work of the Council.

Dr. WILCOX, in closing, said that perhaps his criticism of the Council had been rather too severe. He fully appreciated the magnitude of the task before the Council. It had simply undertaken to do more than it could.

Legal Control Necessary in the Treatment of Drug Habits.—Dr. FREDERICK H. GERRISH of Portland, Me., emphasized the futility of depending upon the victim's will-power. Physical restraint was necessary in almost every

case. And yet if the physician interfered with the freedom of action of the victim, even with his consent, he made himself liable to a subsequent suit for false imprisonment. The only way to reconcile the conflicting interests of physician and patient was by the enactment of a law by which the victim could relinquish his freedom long enough to ensure a cure. Such a law was enacted in Maine in 1905. Dr. Gerrish had heard no complaints that its workings were other than salutary. The paper closes with a statement of the law.

The Value of Physical Training in the Treatment of Neurotic Patients.—Dr. B. E. McKenzie of Toronto said that the first step was to make a positive diagnosis to determine whether organic disease was present. In the management of the neurotic there must be no vacillation on the part of the physician. He must separate his patient from all harmful surroundings, and subject her to a kindly but firm discipline. She must be turned from introspection and egotism and taught to be cheerful, self-reliant, active, and altruistic. The ordinary "rest-cure" fell short in that it was merely negative. For discipline, encouragement, and development, physical training in the gymnasium and on the playground was a most effective agency. It required the assistance of a thoroughly trained and tactful director.

Principles Underlying the Treatment of Tuberculosis. Dr. Francis M. Pottenger of Los Angeles classified the measures employed in combating tuberculosis under six heads: (1) Those which aided in bringing about immunity by endeavoring to restore as far as possible the normal resisting power of the patient—fresh air, hygienic measures, proper diet, hydrotherapy, favorable climate, and suitable tonics; (2) those which aided in bringing about immunity by artificially stimulating the body cells to the production of specific protective substances—vaccination, or treatment with such products as tuberculin; (3) those which aided in establishing immunity by supplying specific protective substances which were produced by vaccinating some animal, such as the horse or cow—antitoxic sera; (4) those measures which caused an increased flow of blood, or lymph, to the seat of infection—Bier's hyperemia, Finsen light, poulticing, local congestive action of tuberculin; (5) remedies and measures which relieved symptoms; (6) measures which relieved secondary infection.

Internal Use of Pyroligneous Acid in Arthritis Deformans.—Dr. Louis Kolipinski of Washington characterized pyroligneous acid as a forgotten drug which, however, well deserved recognition as a therapeutic agent. He described it and explained its chemical composition. It was a dark-red liquid, turning black on exposure. It had been called "liquid smoke." After discussing its physiological action and toxicology, he cited cases in which it had proved efficacious in his hands in the treatment of arthritis deformans. The restoration of function was well shown in the use of the hand and fingers. The claw-like posture, the extended position in which the member was held, the constant watchfulness to protect it from contact, were no longer seen. Flexion and extension returned, and the hand resumed its duties. The patient ceased to complain, unless this continued from habit.

Dr. Arthur H. Hall of Washington related a case of joint disease in which he had used pyroligneous acid with marked success, after the usual methods had failed. The joints affected were those of the jaw and right shoulder. Two drachms of the acid in water were given every three hours. Before eight ounces had been taken the patient demonstrated that pain had disappeared, and after a time motion in the affected joints was satisfactorily restored.

Dr. H. C. Wood of Philadelphia said that undeservedly disused medicines should be revived, and he who revived them deserved credit. But he objected to pyroligneous acid for pharmacological reasons, since it was a complex substance, containing components some good, some indifferent, and some harmful. The tendency of to-day is toward the use of simple drugs.

Dr. A. D. Blackader of Montreal expressed doubt whether valid conclusions as to the value of the agent in such a resistant affection as arthritis deformans could be drawn from a few isolated cases. Sometimes the disease got well spontaneously, and at others it became quiescent and later broke out again.

Dr. Oliver T. Osborne of New Haven suggested that some of the good might have been due to disinfection of the bowel. He discussed the subject of bowel disinfection. He believed that something could be done in this line, and the beneficial action of such remedies as pyroligneous acid in joint pain might in some degree be due to this effect. He did not see how it could do any good in arthritis deformans after bone had been deposited. Some of these patients got well, and no one could tell why or how.

Dr. Kolipinski, in closing, said that in the light of his experience he could not do otherwise than believe in the efficacy of the remedy. He appreciated the force of Dr. Wood's criticism, however, and intended to make the individual components of the acid a subject of further study.

The Value of Chemical Substances Used Hypodermatically to Antagonize Morbific Processes.—Dr. John Blake White of New York read this paper. Hypodermic medication was introduced by Wood of Edinburgh as a strictly local measure. Hunter of London first recognized that it could be used for systemic effect, and now it was universally believed that localization of the injection was not necessary. There was little certainty about the dose given by the stomach. Quinine had been given hypodermically in malarial fever in one-fifth of the dose given per os, with much better effect. It was possible that some morbific processes were combated by antitoxin produced by substances injected hypodermically. The results achieved by him in fifteen years had convinced him of the superiority of the hypodermic method. Remedies given thus were not changed by the gastrointestinal juices; they could be given to those unable to swallow, and when irritability of the stomach existed. The remedies selected should be soluble and unirritating. One should be prepared for idiosyncrasy. Dr. White exhibited a syringe which could be kept aseptic more easily than those in general use.

Dr. S. L. Dawes of Albany said that quicker and more satisfactory results could be obtained if the solution was injected at the temperature of the body. Also, the drug used should be in perfect solution.

The Importance of a Knowledge of the Natural Course of Disease in Estimating the Effect of Therapeutic Measures.—Dr. Alexander McPhedran of Toronto said the universal tendency was to regard the phenomena following a cause as resulting from that cause. In nothing did this apply more fully than in therapeutics. The wish was too often father to the thought. The masses were still imbued with the ancient belief in the mythical power of drugs, and relatively the profession often showed quite as blind a faith. Dr. McPhedran urged that in estimating the effect of our therapeutic measures we should more carefully consider the natural or uninfluenced course of disease. He called attention to the many variations which might occur in the natural course of all diseases, and how readily these could be erroneously ascribed to the administration of drugs. He emphasized this by references to pernicious anemia and its treatment by arsenious acid; to typhoid fever, diseases of the heart, neuropathic affections, and tuberculosis. It was essential that a careful record of the patient's condition be made, with variations in the course of the illness, in order to enable us to direct intelligently the treatment and estimate accurately its effect. With the advent of the laboratory the tendency had been to rely upon it, to the neglect of the proper study of the patient himself.

Dr. B. E. McKenzie of Toronto emphasized the importance of accurate observation of the patient in order that the physician may know the causes which produce definite results.

Dr. Thomas E. Satterthwaite of New York spoke first of intestinal antisepsis. We must distinguish between drugs that killed and those that inhibited the development of bacteria in the intestine. He believed that Dr. McPhedran would agree with him that certain drugs, like mercurials, did exert an inhibitive action, and to this extent they were intestinal antiseptics. Speaking of tuberculosis, he said that when the specific bacillus was discovered the pathologists believed that the cure of the disease was at hand. The claims made then had not been realized, and now the laity was trying to force the profession into the unnatural position of producing a cure when it could not do so. It was true that medicine was not an exact science; neither was chemistry.

Dr. Oliver T. Osborne of New Haven said he believed we could secure some degree of asepsis of the upper intestinal tract. What disease could we treat without first cleaning out the bowel to see what symptoms were left? Cleanliness was next to asepsis; but we could do more than secure mere cleanliness.

Dr. Francis M. Pottenger of Los Angeles said it was true that we were losing sight of the importance of accurate observation of the patient, and improved laboratory methods had tended to bring about this result. Too often we drew our conclusions wholly from the results of examination of the blood, urine, or stomach contents. No class of patients had suffered more in this way than tuberberculous patients.

Dr. A. D. Blackader of Montreal said that the early physicians were too optimistic, their followers were oversceptical, and now we were upon the middle ground.

The Treatment of Postpartum Puerperal Eclampsia.—Dr. D. Olin Leech of Washington read this paper. Postpartum eclampsia differed from the antepartum form. The mortality in the former is less. Treatment consists in the arrest of convulsions and elimination of the poison. Morphine in one-half grain doses was the best remedy to stop the convulsions. Chloroform might be administered, and chloral per rectum was helpful. He highly commended tincture of veratrum viride in 10 to 20 minim doses until the pulse rate fell to 60. It acted like venesection. The poison should be eliminated through the kidneys, bowels, and skin. The bowels should be emptied by repeated enemata, and this followed by a pint of salt solution. Hypodermoclysis might be employed if necessary. Six ounces of milk should be given every two hours, and plenty of water. The potassium diuretics were not advisable. Activity of the skin should be promoted by the use of hot-air baths, or hot packs. He had used the former to good advantage. Pilocarpine was not a safe drug to use. Magnesium sulphate or croton oil may be used as cathartics. Basham's mixture and strychnine were the best remedies in the after treatment.

Dr. H. C. Wood of Philadelphia spoke of the physiological action of veratrum viride. Recent studies had shown that it was not a vasodilator, but the reduction in blood pressure was due to the slowing of the pulse rate. Jervine was formerly believed to be its dominant alkaloid, but it was now known that it played but a subordinate part. The chief constituent, protoveratrine, was a heart stimulant. Thus veratrum viride was a stimulant rather than a sedative. If it did good in eclampsia, it was by bleeding the patient into his own vessels.

Dr. W. M. Sprigg of Washington said the presence or absence of albumin in the urine was not so important a guide as the quantity of urea eliminated. In many cases of eclampsia little or no albumin was present, but deficient elimination of urea was always a danger signal. He believed that the same toxic conditions were present in eclampsia after as before delivery, and the treatment was practically the same, except that in the postpartum form the uterus has got rid of the placenta, the source of the toxins.

Dr. Robert Reyburn of Washington agreed with Dr. Sprigg as to the importance of urea elimination as a guide. He advocated venesection in certain cases, and cited an instance in which the removal of sixteen ounces of blood from a plethoric woman was followed by almost marvelous results. The convulsions ceased immediately.

Dr. Philip King Brown of San Francisco said that the work of Folin had shown that the urea elimination had nothing to do with eclampsia. In a recent article he showed that no matter how great the retention of urea, eclampsia did not necessarily follow. Experiments on patients who had previously suffered from eclampsia pointed to the same conclusion. The only significance was that something else was retained if urea was. He believed that eclampsia was not due to any one cause. For one thing, it was probably due to toxins from the placenta. The thyroids might also play a part.

Dr. W. A. Campbell of Colorado Springs said that he had seen two cases of eclampsia within six months. In both cases the removal of clots from the uterus was followed by cessation of the convulsions.

Physiological Action, Elimination, and Therapeutic Application of Sodium Cacodylate Used Hypodermically.—Drs. Spencer L. Dawes and Holmes C. Jackson of Albany presented this paper. Sodium cacodylate was introduced by Gautier in 1899. During the next four years it was hailed as a desirable substitute for arsenic. In 1903, however, Fraser gave it its *coup de grace*, and, with one or two exceptions, all English and American textbooks deny the possibility of its having either physiological effects or therapeutic value when given hypodermically. The studies of Dawes and Jackson showed that the drug had a distinct pharmacological action (being decomposed and eliminated as arsenates in the urine, feces, and probably the sweat and breath), and had a toxic effect; the urine of the patients yielded arsenates, and reacted to Marsh's test. It also produced many of the therapeutic effects common to the arsenic compounds. The authors set forth the experiments used to sustain this contention. Cases were also cited illustrating its therapeutic value. These included lichen ruber, psoriasis, eczema, anemia, Hodgkin's disease, cholera, gastralgia, and various neuroses.

Dr. H. Van Rensselaer of Albany commended the paper as being thoroughly scientific. He was inclined to take a middle ground as to the value of the remedy. He thought it wise to try ordinary arsenic first, and if that failed to resort to sodium cacodylate.

A Résumé of the Physiology of the Kidney with a View to Therapeutics.—Dr. V. E. Henderson of Toronto read this paper. He concluded that Brown-Séquard's contention, that the kidney had an internal secretion, had lost rather than gained weight. The cells of the tubules undoubtedly excreted urates, hippurates, pigments, and, possibly, creatinin. They were permeable, and in man might excrete water, chlorides, phosphates, sulphates under stimulus, and, under more abnormal circumstances, dextrose. The urine leaving the tubules, though usually more concentrated than the plasma in salts and urea, under a rapid flow more nearly approximated it in salt composition, and might even become more dilute than the plasma. Filtration did not occur; it was rather a diffusion under pressure. He suggested that the term secretion, as applied to the kidney, be dropped. A theory might be advanced in the future based on the following facts: Between the membrane and the substance passing through it some chemical affinity must exist; for instance, a membrane may exist such that water and salt may pass through it, but not such a crystalloid as sugar; when the affinity is slight, in case of a dilute solution, though none of the dissolved substance may pass through, yet with a higher pressure it may do so; the osmotic pressure does not vary with the substance present, or with the temperature; different membranes may allow different crystalloids to pass through, but not the same crystalloids.

Dr. Oliver T. Osborne of New Haven said we could not determine the pathological condition of the kidney by

chemical means. Patients did not necessarily die of kidney disease when albumin was present in the urine, and yet they might do so when none was present. We should make a more careful examination as to salt excretion in order to determine if possible what portion of the kidney was diseased. As to whether the kidney had an internal secretion, the affirmative position must be disproved. It was possible that the kidney formed an antitoxin. This was indicated by the fact that in nonfunctional disease suppression had existed as long as four days without uremic symptoms, whereas the latter almost invariably occurred in organic disease within twenty-four or thirty-six hours.

Dr. Solomon Solis-Cohen of Philadelphia said that in a case of his early practice suppression existed for seventy-two hours without any other symptom than dilatation of the pupil. Dr. Osler confirmed the diagnosis of contracted kidney. The patient died twenty years later of pulmonary tuberculosis.

The Therapeutics of Bright's Disease Based upon Its Etiology.—Dr. William H. Porter of New York read this paper. He drew the following conclusions: 1. All therapeutics, to be successful, must have for the primary object the removal of the causative factors of disease. 2. Hemorrhagic nephritis as such does not exist. It is an occasional modification of the chronic parenchymatous change. 3. Most renal lesions are non-inflammatory processes. The one exception is the exudative class. Most renal lesions are due to overwork of the glands at a time when nutrition is impaired. 4. Both the overuse and defective supply of the starches, sugars, and fats are important factors in the production, maintenance, and cure of renal lesions. 5. Nervous overstrain is also an important factor. 6. Treatment is to be directed both to prevent and cure. 7. It consists chiefly in the removal of causative factors. 8. It calls for a thorough knowledge of chemicopathology and dietetics. 9. Drugs, while not curative, may indirectly produce wonderful results. 10. These renal lesions, when studied from the histological standard only, are incurable. Considered from the physiological and chemical standpoint, a large per cent. are curable. 11. It is difficult to see how surgery can be made to remove the underlying factors. Hence such means cannot be classed as scientific.

Indications for the Radical Mastoid Operation and Its Results.—Dr. W. Sohier Bryant of New York said the indications might be placed in two categories: 1. Those cases of acute mastoid involvement with extensive infection or destruction of the temporal bone, requiring the complete evacuation of all the cellular structures connected with the middle ear and mastoid. 2. Certain cases of chronic suppuration of the middle ear. The results are three: cessation of suppuration, complete lack of external deformity, and greatly improved hearing. After citing cases in illustration, Dr. Bryant concluded as follows: 1. The radical mastoid operation assures cessation of the purulent otitis. 2. It is an operation for the immediate relief of this condition. 3. It may be the operation of final recourse. 4. The hearing is much improved, since in a number of cases the auditory function of the middle ear can be almost completely restored. In a small number of cases there is no improvement in hearing. 5. The cosmetic results are very satisfactory. 6. Paralysis of the facial nerve is a very rare accident in skilful hands. 7. The results are uniformly satisfactory when the best technique is employed.

Dr. Frederick H. Gerrish of Portland, Me., spoke of sinus thrombosis in connection with disease of the ear. A radical operation was necessary to save the patient's life. He cited the case of a child twelve years old, seen two years ago. The temperature rose to 108°. He performed a radical operation, removing the clots, and the child recovered. The general practitioner should remember the possibility of this complication as a result of extension of infection.

Dr. Solomon Solis-Cohen of Philadelphia said that most of the cases he had seen were in children. The patients are in much danger, and we incurred a great responsibility in advising delay. Hearing was a secondary matter. In a number of instances he had known meningitis, brain abscess, and other serious complications to follow neglected mastoid disease. It was worse than appendicitis, so far as danger was concerned. He always advised immediate consultation with a skilled aurist. He cited a case illustrating the danger of delay.

The Non-Surgical Treatment of Exophthalmic Goiter.—Dr. Solomon Solis-Cohen of Philadelphia read this paper. He had recently heard a paper on the surgical treatment in which a mortality of thirty to fifty per cent. was considered a good result; ten per cent. was considered phenomenal. He would be ashamed of a mortality of ten per cent. from medical treatment. He related three cases in which he used the new serum treatment. In early cases it was not necessary to use the serum. Ordinarily the old treatment was efficient, viz., rest, hygienic measures, and drugs, such as ergot, picrotoxin, strophanthus, and thymus and adrenal gland. He tried adrenal first, and generally it proved efficient; if not, he gave thymus, and, if necessary, both together. These failing, he went back to ergot and picrotoxin.

Dr. Philip King Brown of San Francisco asked why relapses were so apt to occur after the serum treatment. They were not characteristic of the disease. His results from medical treatment were about the same as those of Solis-Cohen. *X*-rays were very efficient in reducing the size of the gland; Mayo used them for this purpose before operating. They also reduced the pulse rate. The results from operation in this country, so far as mortality was concerned, were good. He knew of but one death, and that was caused by cutting through the gland and liberating too much secretion in the system.

The Importance of Early Recognition of Nasal Obstruction with Relation to Disease in Other Regions.—Charles H. Knight of New York presented this paper, which was read by title.

The Treatment of Chronic Valvular Diseases of the Heart.—Dr. Thomas E. Satterthwaite of New York read this paper. He first spoke of treatment by baths and exercises, particularly the Nauheim method, the value of which was now generally recognized. The Oertel method was helpful in mild cases. The Nauheim system was adapted to a much larger class of cases, and even when a complete course of baths and exercises was contraindicated it could generally be used to advantage. The particular muscles to be exercised, the duration of each movement, and the interval between them depended upon the views of the physician. It was well for the physician to be present at the treatments in person. The Nauheim method did good by driving the blood into the capillaries, thus relieving the heart and lowering arterial pressure; the improved condition of the circulation promoted metabolism and nutrition; the skin became softer and the urine increased in quantity and specific gravity, showing that the system was more rapidly getting rid of waste products. The method was applicable to any form of heart weakness or valvular disease, whether due to loss of compensation or not, especially when there were high arterial tension, dilatation, and muscular degeneration, provided the muscular relaxation had not gone too far. After discussing massage and baths, the writer turned to treatment by drugs. Strophanthus was becoming better known and was producing better results. It acted quicker than digitalis and slower than the nitrites. Suprarenal extract was being used more and more; it was probably the most powerful heart stimulant we had, contracting both the heart and arterioles. He had found no ill-effects from as much as one-fiftieth grain of nitroglycerin every five minutes in alarming cases. The dose should be increased cautiously in arteriosclerosis. Camphor acted in

a few minutes and was a perfectly safe stimulant. Convallaria has had its day; it was unreliable. Sparteine had come into favor. Caffeine was a mild but rapid stimulant. Digitalis was the most effective remedy in cardiac weakness.

Dr. F. E. Stewart of East Orange said that the varying effects of adrenalin might in part be ascribed to the difference in strength in the preparations employed. Unquestionably some of the tinctures deteriorated on standing; this subject was being investigated in New York, and it was possible that in the future labels might be dated, indicating the age of the preparation. He had used the baths in uric acid diathesis to good advantage.

Dr. Eli H. Long of Buffalo said that the keynote in treatment was heart nutrition. He highly commended the Schott baths. They rested the heart by lessening peripheral resistance, and thus promoted metabolism and nutrition. Even when there was lack of compensation and the case was hopeless as to cure the baths rested the heart and prolonged life.

Dr. Beaumont Small of Ottawa said that the acute and chronic forms of heart disease required different methods of treatment. The chronic forms were particularly troublesome. He asked Dr. Satterthwaite how soon after acute onset he ordered the baths. He thought it well to allow a period of rest before beginning the exercises. The chief value of the baths was in the temperature, although the saline and other ingredients might have some small value. The patients were best treated at institutions, where there were adequate facilities and trained assistants. The main point was the relief of the peripheral circulation when it was congested. He commended camphor as a stimulant. The tincture was the most trustworthy of the preparations of digitalis.

Dr. Oliver T. Osborne of New Haven agreed that institutions were the best places for these patients. The *régime* and willingness of the patients were strong factors. Digitalis was a heart tonic rather than a stimulant; it was an error to give it in acute cardiac failure, or at frequent intervals. Thus it might do harm in typhoid fever, pneumonia, and other acute conditions. There was much poor digitalis on the market. Strophanthus deteriorated rapidly; it should not be diluted with water. He commended the use of nitroglycerin. Adrenalin was being a little overworked; it was not well in these cases to increase the tone of the arterioles too much. It should be remembered that the heart was only a small part of the circulatory system.

Dr. John Madison Taylor of Philadelphia spoke of the influence which could be exerted upon the circulation through vasomotor control by means of gymnastic exercises. The importance of these mechanical measures was often overlooked by those who dealt with heart affections. There was prevalent a woeful lack of knowledge as to the vasomotor system. He had hoped that Dr. Satterthwaite would say more as to the value of mechanical measures.

Dr. Spencer L. Dawes of Albany added his testimony as to the value of strophanthus and its glucoside. It is almost a heresy to speak against digitalis, but there were cases with adequate compensation when it was not applicable. The preparations of adrenalin changed on exposure, notwithstanding the claims of manufacturers to the contrary. He emphasized the value of chloralamid as a hypnotic in heart affections. It was particularly useful in cardiac asthma.

Dr. Howard Van Rensselaer of Albany expressed the belief that the salts in the waters of the baths had no efficacy. It had been proved that salts in aqueous solution were not absorbed by the skin. Shipwrecked sailors soon became insane if they drank salt water; but if they threw over an arm or leg a cloth wet with sea water their thirst was in a measure assuaged; the water was absorbed, but the salts were not. The same thing had been scientifically proved by experiments with potassium iodide and lithium. The good done by the baths was mainly due to the water pressure and temperature.

Dr. Robert Reyburn of Washington said that his experience with the baths had been unfavorable. He had seen no therapeutic effect of long duration. What benefit there was resulted from friction and temperature.

Dr. Satterthwaite, in closing, agreed with Dr. Osborne that the patients could best be treated at an institution. They could not be properly controlled at home. We must distinguish between acute and chronic heart affections. The Nauheim method was applicable only to the chronic forms. Mild cases of arteriosclerosis were suitable for treatment, but when there was a possibility of apoplexy the treatment was dangerous. The baths were given for ten minutes or less every other day, their number depending on whether the patient remained four or six weeks. The temperature was undoubtedly an important factor. Pulmonary gymnastics formed a valuable auxiliary to treatment.

Restoration of Tissue Tonus in the Abdominal Supports.—Dr. John Madison Taylor of Philadelphia said that between the diaphragm and pelvis the body was anatomically and physiologically weak. There was a tendency to inefficiency of the natural abdominal supports, and this tendency was accentuated by weakness of the abdominal muscles from disuse. This inefficiency was greater in some individuals than in others, and it often reached a point where the abdominal viscera were not properly supported. When the supports were adequate there was a relatively slim waist in man and woman alike. When they were inadequate there was a dropped chest and protruding abdomen, and the lower organs were in a state of hyperemia with insufficient drainage; there was a tendency to ptosis and functional incompetence. Ordinary exercises did not reach this part of the body. The Nauheim treatment did good, but it was not sufficient. After a study of thirty years he had come to place reliance on certain exercises which were directed solely to the strengthening of the abdominal supports. He employed artificial supports, belts, etc., until the natural supports had to some degree recovered their tone. Visceroptosis was a serious condition and one that is not to be remedied by the surgeon. His methods had enabled him to restore displaced viscera with marked local and systemic benefit. Time was necessary for a cure. Surprisingly satisfactory results could be obtained after months, or even years.

A Study of the Modern Drug Business in Its Relation to Medical Practice.—Dr. F. E. Stewart of East Orange emphasized the following points: 1. Medicine and pharmacy cannot be practised as disassociated and independent professions, as they are mutually dependent. 2. The practice of pharmacy should be carried on as a subordinate profession to medicine, and the pharmacists should be subjected to the same professional censorship as physicians by membership in societies that are in affiliation with the medical societies. 3. The proper practice of the pharmacological art requires a free materia medica and common standards, jointly established and maintained by the medical and pharmaceutical professions and the manufacturing houses engaged in the materia medica supply business. 4. The practice of pharmacy and drug therapeutics should be limited to qualified and licensed practitioners, and the field of practice should be protected from invasion by unlicensed practitioners who set up as manufacturers and conduct their business in unfair competition. 5. Inventors of new and useful processes and apparatus for the manufacture of materia medica products, who are duly qualified by education, training, and license, and who are members of regularly constituted professional societies in good standing, should be rewarded for their inventions and discoveries by patent protection.

H. C. Wood of Philadelphia did not believe that the science of pharmacology would be advanced by giving it over into the hands of the manufacturers. Their chemists had introduced a few useful drugs, but they were few. The world would be better off to-day had the coal tar drugs never been discovered.

Dr. L. F. Kebler of Washington said that manufacturing chemists were not always given due credit for their work. He was a chemist in a manufacturing house for ten years, and he knew the sentiment without and within. His work there was as honest and sincere as that which he was now doing for the Government. Something should be done to control the sale of drugs by manufacturers directly to the public. The problem as to the matter of trademarks was working out nicely. He referred to the case of a preparation which was claimed to cure all nervous affections, including locomotor ataxia; the decision was that with such claims the preparation had no standing before the court. Finding this out, some of the manufacturers had asked the authorities how they could make their preparations creditable before the new law. This was significant, as it showed that they could be kept in check and that they were inclined to obey the law.

Comparative Clinical Observations of the Results of Different Iron Preparations.—Dr. Eli H. Long of Buffalo reported the results of fourteen tests which were made upon nine patients suffering from chlorosis, or mild grades of anemia, or combined forms. The results were decidedly in favor of the official preparations, as the following summary showed: Iron peptonates, used in 8 observations, produced no improvement in 4 cases, very slight improvement in 2, evident improvement in 1, and marked improvement in 1. The official forms of iron, used in 6 observations, produced no improvement in 1 case, evident improvement in 1, and marked improvement in 4.

Dr. H. C. Wood of Philadelphia said that the system required one-sixtieth grain of iron each day. With every meal we ate more iron than was necessary for the whole twenty-four hours. The iron we gave as a medicine acted not as a food, but as a stimulant to the blood-making organs. True organic, or food, iron had not this property, and therefore could do no good in chlorosis. The iron must enter the system in inorganic form in order to do good.

Dr. Oliver T. Osborne of New Haven said there are too many preparations of iron. He preferred the simpler ones and used the tincture, reduced iron, and sugar of iron.

Dr. D. Olin Leech of Washington said that he preferred the tincture in small doses. He got better results from it than from the more complex preparations.

Dr. Beaumont Small of Ottawa said that he relied mainly upon the tincture, reduced iron, and Blaud's pill. He believed the tincture to be the most efficient preparation.

Dr. L. F. Kebler of Washington commended the unbiased character of the paper.

Dr. James C. Wilson of Philadelphia said that, speaking as a clinician and not as a laboratory investigator or chemist, he believed we could afford to give up entirely the use of the organic preparations of iron, some of which had value, and he was obliged to give them credit. On the other hand, he valued most highly the official preparations. He had had phenomenal success with the syrup of the iodide in diseases of children. In gonorrheal arthritis it had given him better results than any other method of treatment. He could not treat chlorosis satisfactorily without Blaud's pill.

Officers.—The following officers were elected to serve during the coming year: *President*, Dr. John V. Shoemaker of Philadelphia; *First Vice-President*, Dr. Joseph E. Janvrin of New York; *Second Vice-President*, Dr. Frederick H. Gerrish of Portland, Me.; *Third Vice-President*, Dr. Howard Van Rensselaer of Albany; *Secretary*, Dr. Noble P. Barnes of Washington; *Treasurer*, Dr. John S. McLain of Washington.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held April 11, 1907.

DR. GODFREY R. PISEK IN THE CHAIR.

A Case of Latent Hereditary Syphilis.—Dr. John Howland presented a boy, twelve years old, who was very sickly as a young child, did not walk until he was three years old, but who never gave any early lesions of hereditary syphilis. Up to December last he was well. He then began to complain of pain in his knees and difficulty in walking, with some stiffness in the joints. No other joints than the knee were affected. Three weeks ago he developed typical interstitial keratitis, which could be due only to syphilis or tuberculosis. The knee joints were very painful, stiff, and contained accumulations of fluid. This child undoubtedly had syphilitic disease of the knee joints; there was not only an involvement of the synovial membranes, but also of the head of the tibia; there was some tenderness over the head of the fibula as well. Dr. Howland thought that it was well to recognize the fact that, in spite of parental evidence to the contrary, many joints in which they failed to make out other evidences of the disease, might possibly be instances of hereditary syphilis, and they should be given the benefit of the doubt and treated as such. This case improved markedly under antisyphilitic treatment.

Dr. Louis Fischer believed that, as a therapeutic measure, the joints should be aspirated, and he cited an instance showing the improvement that followed such a procedure.

Dr. Herman Schwarz thought the *x*-ray would be of value in making the diagnosis; it would show the enlargement of the periosteum. He did not believe in aspirating joints unless one was prepared to go ahead and institute drainage.

Dr. Louis C. Ager, Dr. Charles Herrman, and Dr. Godfrey R. Pisek discussed the case.

Case of Diabetes Insipidus.—Dr. Eli Long presented this boy, eleven years old, whom he had already shown at the section meeting in January (see Medical Record, Vol. 71, page 331). The boy's condition had not changed to any appreciable extent.

A Case of Diabetes Mellitus.—Dr. Eli Long presented this case at the January meeting of the section (see Medical Record, Vol. 71, page 331). No satisfactory progress had been made under his treatment, and the patient passed from his care. He looked her up the other day and found that she had lived just three and a half months after she fell and struck the back of her head. She was up and about on the day of her death, which occurred very suddenly.

Dr. Louis C. Ager said he had a similar case under his care. The child was over four years old, weighed 34¾ pounds, and passed from ten to fourteen pints of urine, with a record of nineteen pints a day. Some years ago he presented symptoms of tuberculous meningitis, and it was possible that his present condition was due to the presence of a slight basilar meningitis. He briefly referred to what had been done with pituitary body extracts in the treatment of these cases.

Dr. Herman Schwarz reported the case of a boy, twelve years old, who passed 11,000 c.c., or about thirteen quarts, of urine daily. A differential point he gave between polydipsia and polyuria was that if some diuretic were given, it would increase the amount of urine in the former condition, but would have no effect in true diabetes insipidus.

Unexplained High Temperature in a Child.—Dr. Louis C. Ager reported the case of a twenty-one-month's-

old child with a negative family history. The patient was the third child, and all the children were healthy. On March 6 the child had a little fever, a moderately distended abdomen, reddened tonsils, and calomel was given in divided doses. On March 9 the abdomen became markedly distended, and the respirations were rapid. The lungs were apparently normal. A tentative diagnosis was made of pneumonia and high saline irrigations were given, which brought away a mass of yellow feces. At 6.15 the rectal temperature was 106°. The chest examination again proved negative. Aconite was given in minim doses. On March 10 the condition was about the same. Nothing was found in the urine. The child made a good recovery. Examination for pneumococci and plasmodium malariæ were negative.

Dr. Charles Herrman said that the reddened throat and irritability of the child pointed to a possible diagnosis of grippe.

Dr. Louis Fischer could see nothing in the way of a diagnosis except an autointoxication occurring in a milk-fed infant. He asked if indican was found in the urine.

Dr. Ager replied no.

Dr. Theron W. Kilmer thought this might be a case of status lymphaticus.

Dr. Ager said that the diagnosis he made was intestinal grip infection.

Dr. Pisek inclined to Dr. Fischer's diagnosis.

Dr. Bartley thought that it might have been a case of colon bacilli infection.

Sarcoma of the Kidney in Children, with a Specimen.—Dr. William Shannon read this paper and presented a specimen. A brief history of the case was as follows: The child was three and a half months of age. The family history was good, there being no history of cancer, tuberculosis, or syphilis. Both parents were living. The patient was well up to three months of age, when there was an enlargement, especially on the left side, noticed. Ten days later the abdomen became enormously distended and the bowels failed to act. When he saw the child he was fairly well nourished, but pale, and had an anxious expression of countenance. Dyspnea was marked. Examination of the heart and lungs proved negative. The abdomen was enormously distended and the cutaneous blood-vessels were much dilated. Upon palpation the abdominal walls were exceedingly dense and hard yielding. A semi-solid mass occupied the left side and extended beyond the median line. It was free from nodules. It was not continuous with the spleen or liver. There was tympany on the left side. A diagram showing the situation and size of the mass was presented. A diagnosis of sarcoma of the left kidney was made and operation advised. Three days later the patient was referred to the hospital and operation was performed. Twelve ounces of fluid escaped with the tappings, and, no doubt, much more was lost in the abdomen. There were adhesions to the peritoneum below the mesocolon. The kidney was pushed forward and to the right. The pedicle, therefore, came from behind instead of at the side. The tumor was removed and with but little bleeding. Three cigarette drains were inserted and the operation was completed as usual. Death ensued eight hours after operation. The tumor weighed three and a half pounds and was eight inches in diameter.

Dr. Louis Fischer said that the age of the child and the size of the tumor were very interesting features. He asked Dr. Shannon if there were any edema of the lower extremities or if any superficial veins were enlarged.

Dr. Shannon replied that some of the superficial veins were enlarged, but there was no edema of the lower extremities, penis, or scrotum. The constipation was caused by the pressure of the growth.

Remarks on the Exudation Diathesis of Czerny.—Dr. A. Hymanson read this paper and said this condition affected children in different degrees and manifested itself in the first weeks of infancy. The parents might be strong, but the children were weak. There might not be any gastrointestinal disturbances whatever, yet the children would not thrive. Some children might go on gaining in weight, but there appeared to be some trouble in metabolism. No other manifestation than a seborrhea of the scalp might be present; this, if irritated, might lead to an eczema. Scrofula was always common among children. Prurigo might be the only symptom evident. The skin might become thickened and covered by scales or crusts. Intertrigo was quite common. In very nervous children there was much itching of the skin, of a severe type, and the scratching might infect the neighboring glands. This explained the presence of enlarged glands in these patients. The various mucous membranes were likely to become involved and inflamed. The trouble must be due to some constitutional dyscrasia. There was constipation, fetor of the breath, and anemia. In the majority of the cases the trouble began in the nose or throat. It had nothing to do with tuberculosis, although tuberculosis might be a sequela. According to Czerny there were three indications to be carefully looked after in the treatment, viz., careful feeding, attention to the condition of the nervous system, and the avoidance of intercurrent affections. Each case must be separately studied. In children in the second year of life a vegetable diet was best. Children should be given plenty of water to drink, but very little milk, no butter, or sweets. The feeding in the first two years of life was very difficult. Great care should be taken that the patient did not get too much fat. Because the patients did not thrive on the mother's milk was not always because the milk was bad, but because of the condition of the gastrointestinal mucous membranes. Great care should be taken not to overfeed. Weaning was beneficial in some cases, especially in curing the skin affections. He cautioned against speaking of the trouble in the patient's presence. Send him to school, and do not teach him at home. Dr. Hymanson then described Czerny's treatment, and he cited a case to show the value resulting from diminishing the feedings.

Dr. Charles Herrman called attention to the publication of Dr. Holt on disturbances occurring in infants due to relatively high fat percentages and who reported five cases. In one case there were attacks of urticaria; in two, obstinate eczema was present; in the other two, the condition was described as an exudative diathesis, a relatively low capacity for fat digestion. Each child had a limit in the digestion of fats beyond which it was not safe to go. There seemed to be some constitutional derangement which was associated with a low capacity for fat digestion. Since the publication of Czerny's article two years ago, Dr. Herrman had been studying these cases, and those that most interested him were cases of facial eczema. They were quite typical and could be readily diagnosed. It had been mentioned in the literature that cases of eczema occurring in infants were improved when they became attacked by some acute infectious disease, such as pneumonia. The cases improved rapidly if the number of feedings and the quantity of food given were lessened. He gave sodium benzoate, five to ten grains, three times a day, according to the age of the baby.

Dr. Louis Fischer presented a photograph of a typical geographical tongue. The patient had an epithelial desquamation of the tongue, with marked fetor of the breath, which was due to the cheesy fermentation occurring in the lacunæ of the tonsils. Dr. Fischer said he wished to emphasize one point, that it was a bad plan to believe, because a baby was fat and gained in weight, that it was a perfectly healthy baby and metabolism thoroughly established. Too much weight was placed on the value of the scales. The dietary and hygienic part of the treatment in these cases had not been sufficiently emphasized. The mass of the people should be taught to give up wrong conditions, and made to know more regarding their diet and hygiene.

Dr. T. S. Southworth said that there was too much of an omnibus classification and too many symptoms described under exudative diathesis.

Variation in Fat-Content of Cow's Milk. A Study of the Fat in Certified Milk Delivered in Brooklyn During 1906.—Dr. E. H. Bartley read this paper. He said that home modification of cow's milk for the preparation of infant's food was the most popular method of the present day. The problem of securing pure, clean milk had practically been solved by the Milk Commission. It was now time to secure more uniformity in the composition of the milk than they had heretofore obtained. Wide variation from day to day were undesirable and sometimes disastrous. Having observed in infants fed upon modified milk disturbances on certain days, which were not seen on other days, it occurred to him that perhaps there were certain variations in the fat on certain days which might account for this. He began to make a study of the variations in the fat of the milk served from one dairy, and soon found greater variations than he had supposed to exist, and he believed the results of this study might be interesting. He had had tabulated the results obtained in the weekly estimations of the fat in the certified milk sold in Brooklyn as furnished by the chemist, Dr. Moak, during the year 1906. This milk was furnished by eight farms and was sold by eight dealers. The results were given by months, which was the average of from four to six examinations each month. The greatest variation in any month was 2 per cent., while 1 per cent. was not unusual. The average of the whole milks which gave between 4 per cent. and 4.4 per cent. of fat gave 16.3 per cent. of fat in the top 8 ounces. Those milks which contained from 5 per cent. to 5.2 per cent. of fat gave a top milk containing an average of 19.5 per cent. of fat. It was shown that the fat in ten bottles varied from 4 per cent. to 5.2 per cent., and the fat in the top 8 ounces varied from 16 per cent. to 20 per cent., or a variation of 25 per cent. Incidentally it was observed that the 4 per cent. milk gave about 16 per cent. fat in the top 8 ounces, which was 2 per cent. higher than he had hitherto found it to be, and higher than it was generally stated to be. This meant that they had been feeding infants with a larger percentage of fat than they had intended, or thought they were feeding. The effect of this was that when they thought they were feeding 2.8 per cent. of fat, they were actually giving from 3.3 per cent. to 4.2 per cent of fat. When they thought they were giving 3.5 per cent. they were actually giving from 4.1 per cent. to 5.2 per cent. The difference between 3.5 per cent. and 5 per cent. of fat in baby's food was a matter of no small importance and probably accounted for some of the troubles on certain days. The cause of the variations might be in the methods used in bottling, or it might be in the breeds of the cows in the stables. By proper mixing of these milks an average milk of a medium amount of fat could be obtained. The results presented were not intended to throw any discredit upon the process of home modification of cow's milk, but to suggest that some efforts be made to correct a manifest defect in the handling of the milk. There should be more care exercised in mixing the whole product of the milking before bottling. The only way to obviate sudden and great variations was to standardize the milk. This should be done with as little manipulation as possible, and might necessitate a return to the practice of bottling at the creamery instead of at the farm. In either case it would be necessary to have frequent estimations of the fat from each dairy, and pointing out to the dairymen how to mix the milk from the various cows to secure about the right composition. This would be a more satisfactory method, he believed, than that sometimes adopted of separating and recombining the skim milk and cream. For infant feeding Dr. Bartley preferred 4 per cent. rather than a richer milk. It seemed to him feasible to have a dairy produce a milk that would yield between 4 per cent. and 4.5 per cent. fat without unnecessary manipulation or trouble by mixing the milk of selected cows.

Dr. Henry Dwight Chapin said that in the assays made at the hospital, where they used certified milk, no such wide variations had been noted as Dr. Bartley's figures indicated. The assays for two or three years presented a variation of about one-half of one per cent. An important thing was to see that the ratio between the fats and proteids was all right. In the young baby the ratio should be three to four; in older children two to three. Infant feeding would be more successful if this ratio was observed. The milk in New York was close on to 4 per cent., but Dr. Chapin preferred a 3 per cent. milk. High fats did not mean high proteids, although the ratio was about the same up to 4 per cent. A very fat milk did not run such a high proteid content. Dr. Chapin preferred to consider three layers of the bottle, viz., the top 9 ounces, with the ratio 3-1; the top 16 ounces, with the ratio 2-1; the top 20 ounces, with the ratio 1½-1. He believed it would be better to bottle the milk at the creamery than at the farm because of better facilities. He was not a believer in separating the milk and then recombining it. Whenever one interfered with the natural emulsion one was likely to get into trouble.

Dr. Roland G. Freeman said that for household purposes most people preferred a high percentage of fat; but for infant feeding he preferred a 4 per cent. fat. Top milks he believed to be a very uncertain method of infant feeding.

Dr. T. S. Southworth said that the estimates presented by Dr. Bartley were made from a special milk, milks that were properly bottled under special regulations. Consequently the variations found might not appear in the New York milk, where the milk was brought from larger and more numerous dairies. The less normal child tolerated fats badly, and therefore it would be a great advantage if they used a milk with a lower fat content. The systematic feeding of babies from the top milks of two bottles, he believed admitted a great many possibilities of trouble. There were cases in which harm was done because of the shipment of milks from the individual's own farms, where fancy cattle were kept. In analyses that he had had made of such milk he had found as high as 7.5 per cent. of fat in two, and 7 per cent. in another. High fat percentages in milk was another cause of eczema.

Dr. Moak said that he could not say what the variations in mother's milk were from day to day covering a period of ten days, but that cow's milk varied greatly.

Dr. E. H. Bartley closed the discussion.

Books Received

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Yearbook of the United States Department of Agriculture, 1906. 8vo, 720 pages, illustrated, muslin. Government Printing Office, Washington.

L'Amnesie. Par les Drs. G. Dromard et J. Leassort. 12mo, 258 pages, muslin. Felix Alcan, Editeur, Paris.

Nouveau Traité de Chirurgie: Les Grands Processus Morbides; Traumatismes, Infections, Troubles Vasculaires et Trophiques, Cicatrices. 8vo, 584 pages, illustrated, paper. J. B. Baillière & Fils, Paris.

On Treatment. By Harry Campbell, M.D., B.S., F.R.C.P. 12mo, 421 pages, illustrated, muslin. William Wood & Company.

A Dictionary of Medical Diagnosis. By Henry Lawrence McKisack, M.D., M.R.C.P. Lond. 8vo, 583 pages, illustrated, muslin. William Wood & Company.

The Essential Similarity of Innocent and Malignant Tumors. By Charles W. Cathcart, M.A., M.B., etc. 4to, 79 pages, illustrated, muslin. William Wood & Company.

Surgical Suggestions.

Dermato-Veneral Don'ts.—Don't think that syphilitic eruptions never itch. They may in hairy parts, or accidental causes may produce pruritis. Don't suppose that itching about the mons veneris is always symptomatic of pediculi pubis. Don't depend upon internal treatment to cure all local syphilitic lesions. Don't promise a cure for psoriasis; it is certain to relapse at some time. Don't confine all your treatment of skin diseases to local measures exclusively. Don't use irritating remedies on acute skin diseases, or vice versa. Don't discourage syphilities; but don't give them too much hope; let them understand the gravity of the disease. Don't deny that you give mercury in syphilis; make your patients know that it is an absolute necessity in the proper treatment of their disease. Don't mistake mosquito bites for measles; look for the small scarlet point in the center. Don't call an eruption of wheals an urticaria when it is bed-bug bites; examine the bed, if necessary. Don't take a bee's or a hornet's sting for a boil; pull out the sting and be persuaded. Don't call every macular erythema a syphilitic roseola. Don't frighten your syphilitic patients or they will desert you.—*American Journal of Dermatology.*

Burns.—After thorough cleansing and disinfection of the injured area has been carried out, the choice of dressings is a large one. That which is easiest obtained and most generally applicable in the early stages is a hot boracic fomentation, which may be changed every four or six hours. Indeed, in many cases these fomentations are also the best, if there is any chance that the first cleaning is not as thorough as might be desired. On the other hand, if the first cleaning has been thorough and there is no particular factor predisposing to sepsis, a dry dressing is better, for it need not be changed so often and, therefore, the patient need not be so much disturbed. The eucalyptus ointment (B.P.) spread on lint is, perhaps, the best application; it is, however, rather expensive and some people object to the smell. A dressing composed of boric acid gr. xx. mixed in ʒj. of soft paraffin is good, but is hardly antiseptic enough, even for a well-cleaned burn. Picric acid solution (5 per cent.) may be used, but it has no especial advantage, and its staining properties make it a very difficult dressing to put on without doing damage to sheets and clothes. A very good dressing is a powder consisting of salicylic acid 1 part and boracic acid 5 parts, powdered on and covered by a piece of dry lint; but it is apt to stick and makes the redressing very painful; also it smarts for some time after it is applied.—*The Hospital.*

Tuberculous Peritonitis.—The treatment of tuberculous peritonitis by injections and notably by tincture of iodine has sometimes given good results, but in certain cases these injections have been known to provoke grave symptoms of collapse. To obviate these accidents Prof. Capperoni substituted for the tincture of iodine iodoform suspended in glycerine in the proportion of five per cent. The quantity injected varied with the age of the patient; in adults he injected the full amount (5—100), while in children the dose was thirty grains in a drachm of glycerin. The injection was made in all cases before tapping the ascites, so as to avoid a too rapid absorption of the substance. After the injection and for a few hours the temperature rose to 102°, but gradually diminished during the three or four days following and caused no trouble. The patients were kept for a week on milk diet to obviate any temporary albuminuria.—*Medical Press.*

Skin Grafting.—A mixture of epithelial scales and blood from the lower layer of the derm is used by Noesske (*Deutsche Zeitschrift für Chirurgie*, Vol. lxxxiii, No. 3, 1906) as a substitute for Thiersch grafts. The graft material is prepared as follows: The area is shaved and cleansed, and the skin, held stretched by the left hand, is scraped with a razor held at right angles to the surface. The dry, horny layer is discarded, and the scraping then continued in the lower layer of epidermis until punctiform hemorrhages occur. These deep scrapings are spread directly on the ulcer in a thin, even layer. As compared to the Thiersch method, it has the very great advantage that only a small area and a slight operation is required to obtain the material, and therefore autoplasty is always possible; and secondly, there is no trouble in covering irregular or concave surfaces such as those following mastoid and other bone operations. It heals, however, less rapidly, than the Thiersch grafts, and gives a less elastic skin. It is especially adapted to very large and irregular surfaces.—*Therapeutic Gazette.*

Medical Items.

Glycogen Contained in the Maternal Liver in Pregnancy and the Puerperium in the Placenta, and in the Liver of the Fetus.—E. Opocher, after experiments on the glycogen contents of the fetal and maternal liver during pregnancy, gives us his conclusions. In pregnancy there is an increased amount of glycogen in the liver, but its accumulation is not regular and progressive, and is greater in the last months of pregnancy than earlier. This increase depends on changes in metabolism, and its variation depends probably on the amount of glycogen needed by the fetus in its development, which is greater during the earlier months. The increase in glycogen takes place to provide for material needed in lactation, for the exigencies of labor, and to aid the system in eliminating the poisons that are thrown into the circulation during pregnancy. The glycogen in the placenta maintains its equilibrium throughout. In the first days of the puerperium the reserve of glycogen, which is no longer needed, rapidly disappears.—*Annali di Ostetricia e Ginecologia.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended August 23, 1907:

AN ACCOUNT OF THE DESTRUCTION OF MOSQUITOS IN THE "ORIGINAL INFECTED DISTRICT" IN THE NEW ORLEANS EPIDEMIC OF 1905;

TOGETHER WITH YELLOW FEVER STATISTICS OF THAT DISTRICT.

By T. D. BERRY, B.S., M.D.,

PASSED ASSISTANT SURGEON U. S. PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

THE yellow fever situation in the city of New Orleans in the last days of July, 1905, was discouraging. The number of cases was increasing daily and the number of new foci, or blocks, in which cases had occurred was also increasing. The situation resembled that of a conflagration in which the flames had overleaped their bounds in spite of the utmost endeavors of the firemen, and brands and sparks falling afar were kindling new flames.

The largest non-immune population in the history of the world was exposed to this disease rapidly spreading, and with an old-time malignancy not manifested on its last visit to New Orleans. According to the history of past epidemics in Southern cities the disease had burnt its way through the non-immune population until frost, and with great loss of life. The epidemic had begun this time in early summer, as had the worst previous ones, with a mortality of over thirty per cent. and with a small section of the city already being scourged as the city at large had been in 1854 and 1878.

It was true that the carrier of the disease, the *Stegomyia callopus* mosquito, was now known, and that the spread of yellow fever had already been fought and conquered along modern lines. It had been eradicated from Havana by Surgeon Gorgas of the Army after a good start had been made in the spring of 1902 while the disease was quiescent. Still it had managed to linger along until the latter part of September, when the last official case was reported, in spite of the fact that Havana was a city only fifteen per cent. of the population of which was estimated by Major Gorgas as non-immune. Dr. Gorgas, moreover, had the advantage of military power in carrying out his sanitary measures. Again, the late P. A. Surgeon Richardson of the Public Health and Marine-Hospital Service had in the early summer of 1904 stamped out the recrudescence of yellow fever in Laredo, Tex. Against these two successes where fortune favored the sanitarian there could be counted failures.

The situation in New Orleans was somewhat similar to that of Laredo in 1903, as the disease was widely prevalent among an alien people, this time the Italians, clustered together in their own quarter near the French market. However, their leaders were active and outspoken and united with the general public of the great Southern city in sympathizing and cooperating with the yellow fever fighters. But it soon became evident that the epidemic had gained a firm foothold and was rapidly getting beyond all control, for though the disease was kept in check in the original infected territory new foci were appearing all over the city. When this was clearly perceived the city did not hesitate to call on President Roosevelt for the aid of the Public Health and Marine Hospital Service. This was promptly furnished by Surgeon-General Wyman of this Service, who detailed over twenty commissioned officers for duty in the city and appointed double that number of local physicians to engage in the fight under the command of Surgeon Joseph H. White of the Service. The result of that summer's fight under the personal direction of Surgeon White is now history. None of the doctors engaged in the fight in the city lost their lives from yellow fever, though several were stricken with it. The physicians outside the city who fought the disease were not so successful, for Dr. Shanley at Baratraria, La., Dr. Anderson at Tallulah, La., and Dr. Rausch at Hamburg, Miss., paid forfeit with their lives, and thus added their names to the long list of medical men who have died as soldiers on the fighting line against yellow fever. However, shortly after the epidemic was over, P. A. Surgeon Richardson, the energetic and efficient executive officer of Surgeon White during the epidemic, succumbed to typhoid fever in New Orleans. It was my honor and pleasure to be more closely associated with him during that long summer's fight than any one else, and I knew of the strain on him as one trying day succeeded another, during which with his happy optimism he would divide cares with, and infuse hope and energy into, the different ward commanders. At night he would take off the day's mask and reveal himself as the tired and exhausted man, worn and harassed by the worries of the day. His vitality and reserve were used up, so that when typhoid fever attacked him he made little resistance. His death occurred, too, at a time when fresh honors were in store for him. He had been invited by the Republic of Honduras to undertake the task of ridding it of yellow fever and was on his way to that country when stricken. He died in his native city of New Orleans as truly a martyr for it as if he had died of yellow fever itself.

It was at the request of Dr. Richardson, then acting as the aid of Dr. Kohnke, the city health officer, that I was detailed for duty there on July 27. I arrived in the city on the night of July 30, and the following morning I was placed in charge of a fumigation headquarters, established July 30, and located within a stone's throw of the French market. The territory surrounded by Esplanade avenue on the north, N. Rampart street on the west, St. Ann street on the south, and the river on the east, and comprising about forty blocks, had been officially designated as the "Infected District," and it was in this district that I was directed to take charge

of the fumigation. This district had already been organized, covered by lay and medical inspectors, and the emergency yellow fever hospital was located in the same block as my own headquarters in the heart of the infected portion.

A few minutes after my arrival I walked into a scene that afterwards became familiar. A fumigating gang was standing in the courtyard of an Italian tenement house. A chorus of frantic wailing women were expostulating with the foreman of the gang, crying children and sullen men were standing near. A glance through half open doors showed sick on their beds in several rooms. The Italians could not understand the intrusion. Some thought that the sulphur fumes were a poison intended for them by the Americans, who were also poisoning their water with kerosene. Even the more enlightened ones wanted fumigation deferred until all the sick had recovered. To have waited until the disease had burned itself out in a large tenement house was impracticable. So finding that none were critically ill at the time orders were given to fumigate all parts of the house not occupied by the sick.

I quickly learned that the proper handling of a large tenement house took several hours' time for a gang of six men. Moreover, there were many blocks of such buildings, two, three, and even four stories high, with from twenty to forty-five rooms each, and the rear of the buildings surrounding or partially surrounding courtyards. The sides of the houses forming the court were lined with galleries, and the courts themselves contained a rookery of small dwellings, sheds, and outhouses, often vine-grown. All of these buildings, sheds, galleries, trees, vines, could be considered as possible, if not indeed probable, hiding places of the *Stegomyia*. Although it was perfectly understood that this mosquito was one of short flight, yet in the neighborhood of the French market, where the historic old Spanish and French houses still remained, it was a shorter distance from the rear of one house to that of another, than from some rooms of the same house to other rooms; while separate in front, the rears of the houses were so joined together by rear porches that several were practically under one roof.

It was quickly seen that the force to work with was inadequate, and as fast as they could be trained new fumigation gangs of six men each were broken in until sixteen were at work. And as soon as the force was sufficient, extra gangs were started at block work. One gang starting at each corner of a block, the four gangs completed it in two days. In this way the unknown foci were reached as well as the known. In about two weeks three-fourths of the district had been covered; the remaining portion, which was only slightly infected and more thinly populated, being spared. The local part of the epidemic being then under control, the force of men was rapidly reduced, trained fumigation gangs being transferred to other wards of the city.

Early in the struggle it was noticed that all the *Stegomyia* mosquitos were not, and could not be, killed by one fumigation of the rooms of the house. Some of the insects would naturally be out of the house in search of water. The underside of galleries, outside stairs, the vines, trees, piles of lumber and rubbish, the cisterns, and water barrels were all harboring places for the infected or non-infected mosquitos. The problem of the destruction of these mosquitos was met in two ways: One was the repeated fumigation of a house, especially if badly infected, and the other was the destruction of mosquitos by the steam blast. By this method a current of live steam under high pressure was sprayed through a nozzle on vines, rubbish piles, and all out-of-door places that could harbor a mosquito. It was under perfect control, and the undersurface of a dark gallery could be sprayed down systematically as if the stream was water instead of steam. Not all mosquitos routed out by this steam blast were killed, but many were, and this helped to lessen the problem.

It was my good fortune, as the officer in charge of the first large ward headquarters, to have the first chance at the unemployed of the city. Among them I secured about all of the theatrical billposters who were then out of employment. With these men trained in the use of paste and brush, better and better closing-up work was done. Archways, even as large as ten feet across and as high, were rapidly covered by successive sheets of 36-inch roll paper and reinforced by diagonal strips of narrow paper. When well put up over archways, or doorways when the door was lacking, these paper doors were as tight as a drum head and as impervious to smoke as the wall itself. Often the rear of a house was taken up by these archways. In one house, built in the form of a quadrangle about a court, we found the court itself lined with these arches. This house, 714-724 Hospital street, which, during ante-bellum days, had been a slave quarter, was now occupied by Italians in front and the rear part was used as a stable. A veritable explosion of secondary cases had occurred in this house, but after turning over fifty men into this courtyard all of the arches were papered across and every room in the place, excepting those of the sick, were sulphured at one time. No more cases occurred in this house. A large house on Chartres street was similarly treated, and open spaces fully twelve by thirty feet were papered across. A similarly satisfactory result followed in this house. Leaky sheds, outhouses, and even semi-closed spaces, such as passageways, were made into closed spaces by this papering process. Large sheets of white pepperill cloth or sheeting were also used to advantage when they could be nailed on wood. This substance is unlike paper in being leaky, yet it held a sufficient amount of the sulphur fumes to destroy mosquitos.

The agents used for the destruction of live mosquitos were sulphur, pyrethrum, and tobacco. Sulphur was burned in pots, and the 10 and 12-inch skillets were found to be most satisfactory. Their large surface area allowed the maximum amount of sulphur to be burned in the shortest amount of time. Pyrethrum was found to be uncertain in action and for that reason unsatisfactory, and under the circumstances dangerous in giving a false sense of security. Tobacco proved to be ineffectual and unsatisfactory. The mixture of camphor and carbolic acid, known as culicide, did not come into use until after this fumigation headquarters had been closed.

A supervisory control was exercised over the lay inspectors and oilers working in the district. No screening was directed from the headquarters of the "Infected District," the amount of work in the way of fumigating alone making it at the time it was in operation the largest and busiest headquarters. After a sick room was screened the place was kept under observation to see that the screening was not disturbed. After some screen doors were found propped open, and the screen wire of the window cut and slashed, warning cards printed in English and Italian were posted on doors stating that this offense was sufficient cause for the forcible removal of

the patient from his house to the yellow fever hospital. After two forcible removals of patients for this offense, no further trouble was experienced. Wherever possible patients were persuaded to leave their homes and go to the Yellow Fever Hospital. When they were without family and friends to care for them they were forcibly removed. In one case a patient was willing to go to the hospital, but his family, particularly a brother, strenuously objected. All of his objections ceased when this solicitous brother was called to one side and promised a place on a fumigating gang. He instantly became such an earnest advocate of the removal of the patient to the hospital that his counsel prevailed. This proved to be to the great good of the patient, who had a most severe attack and only recovered after most careful nursing, which he could not have had at home. Early in the work it was found advisable to employ a sprinkling of Italians among the workers, and one was placed in each gang as an acting interpreter. As these men could not help being impressed with the good accomplished, they became missionaries among their own people. And to the good influence of these workers I attribute much of the acquiescence of their people in the sanitary measures employed.

The character of the fumigation of a house depended on whether the case was removed to a hospital or not. In the former case the infected house and the ones on either side, also the one in rear, if closely abutting, were simultaneously fumigated. This one fumigation sufficed, unless other cases developed. On the contrary, when the case was treated at home, as much of the house as possible was fumigated at the time without unduly disturbing the sick. The houses on each side, when close, were also thoroughly fumigated. On the recovery or death of the patient the infected and its neighboring houses were again fumigated. Towards the last, when the origin of a case could be traced to infection outside of the district, the neighboring houses were spared. Whenever a new case occurred, however, in a house previously fumigated, it was fumigated again and again until cases stopped occurring. In one such house, 1217 Royal street, case after case occurred in spite of numerous fumigations. A search of the neighborhood showed that in the back yard of one of the adjoining houses were a large number of bottles hidden in some high grass. Water in these bottles contained numerous *Stegomyia larvæ*, and the cool grass was apparently the daytime refuge of the infected mosquitos. After this discovery and the remedy, one more fumigation of the house sufficed. Whenever cases kept occurring in a house a prolonged search by myself usually revealed a mosquito-breeding place in an unusual locality that had escaped the lay inspectors.

At the outset of our campaign the measures used were, I must now confess, strenuous; possibly, in the light of subsequent experience, more forcible than necessary, but then with sick and dying in every direction, and the hearse the vehicle most conspicuous on the streets, it was no time to go by usual standards, and the comfort and personal and property rights of the individual suffered. The district in August was partially deserted, and many houses or parts of houses were found locked. Usually the occupants had really gone away, sometimes they merely ran away when they saw the fumigation carts approaching. Threats to break open doors often caused keys to be produced, and when they were not the doors were ruthlessly forced. After fumigation the doors were again nailed up and printed notice affixed to them that forcible entrance had been made by the sanitary authorities. As a matter of course vigorous complaints followed this procedure. After the epidemic was gotten under control, the expedient of merely sealing up rooms was tried. The parlors of the better class of residences would contain many articles of furniture and furnishings that could be injured by sulphur gas. Such a room was first searched for objects, such as flower vases, that might contain water, and then the room was prepared as for a fumigation by sealing across the fireplace, if there was such, and across the cracks of windows and doors from the inside when these were not tightly fitting. The door of egress was then closed and sealed across from the outside. A printed notice was then placed across the door stating that the room would not require further treatment if the seal was unbroken. On the termination of the case, and after a complete fumigation of the rest of the house, this room could then be opened in confidence that no mosquitos had survived, for these insects cannot exist without water for over three or four days. As far as I know this method of killing mosquitos had never been used before with practical results, and I regard it as an important adjunct method of killing the insects. By chinking up cracks or doors and windows with cotton instead of pasting over them, this method is absolutely without injury to a room or its contents, a claim that cannot be made for any other method of killing mosquitos.

Another expedient tried in the early part of the campaign at the request of City Health Officer Dr. Kohnke, who was solicited by some experimenters in Texas to give it a trial, was the placing of mosquitos traps in sick rooms. These consisted of new molasses kegs about one-quarter filled with water and with a hinged trap door. They were placed in a sick room in the afternoon with the request that the trap door, 6 inches by 6 inches, be left open during the night and the next morning be closed, the idea being that the mosquito would go into the keg for water and finding it a suitable resting place would decide to spend her spare time in it. In the morning a messenger sealed the tops securely and brought the kegs to my office. No mosquitos were ever found in them.

The district being compact, ordinary push carts were used for the transportation of supplies by the fumigating gangs. They were supplied on leaving headquarters in the morning with sulphur, alcohol, paste, 2-inch, 6-inch, and 36-inch roll paper, pots, large paper shears, hammer, tacks, and nails. The foreman of a gang, when given an assignment of houses, would proceed with his gang to the first house, explaining his mission to the householder and after gaining his acquiescence would go ahead with the fumigation. If his eloquence or that of the interpreter failed, then I was sent for, and if my advice did not prevail, one or both of the two policemen detailed at my headquarters were summoned. The sight of the bluecoat was usually all that was necessary. Once a desperate negro assaulted a policeman with an axe; the policeman, who happened to be without his revolver, courageously stood his ground and fought with his club, finally knocking out his assailant by a lucky blow.

After the men had removed damageable articles from a house and had pasted up the cracks to make everything tight, a rough estimate was made by the foreman of the cubic capacity of the space to be fumigated, and two pounds of sulphur to the thousand cubic feet was allowed. In a few instances

I was able to move patients in their first day of sickness to a part of the house that had already been fumigated while their own sick room was being fumigated. A stretcher was bought for this purpose, but was used only a few times. In few cases was entrance made to the sick room of the patient until they had either died or were able to be on their feet.

An interesting way of noting the number of mosquitos in a house was to spread a sheet over the floor in front of a window of a room which was being fumigated. The other windows of the room were darkened and when the mosquitos were routed from their hiding places by the constantly increasing sulphur gas in the room they would fly towards the light, there to hover about until they fell asphyxiated on the sheet. Afterwards it was enough to convince the most skeptical doubter of the mosquito doctrine to see in a room where a patient had just died of the fever a dozen or two female *Stegomyias* dead on the sheet with their abdomens in various stages of distention from the blood of the late patient, and to know that products of the absorption of this blood would have been duly injected into some one else's system had not the mosquitos been arrested in their career.

However, daytime entrance into even the most infected houses during the epidemic did not prove particularly dangerous. Of my force of over 100 men, nearly all non-immunes, only two, besides myself, suffered from attacks of yellow fever. In the case of my men I could not eliminate the possibility of their being infected at their own homes, for they lived in infected neighborhoods. As for my own infection I attribute it to having stayed in a badly infected house until after dark, just about four days before the onset of the disease, although I do not know when I was bitten. The bald statement that over 100 non-immunes spent about eight hours daily for weeks working in the worst infected houses of the city, with a morbidity of three per cent., and none of them positively attributable to daytime infection, is a good illustration of the almost purely nocturnal activity of the female *Stegomyia* of sufficient age to transmit yellow fever. I believe the experience of the other ward commanders regarding their men was about the same as mine. The former practice of towns having daylight communication with safety with infected cities has now a sufficient explanation when the cause of the transmission of yellow fever is known.

The historic old French market, covering several blocks, was given an "open" fumigation, the idea of P. A. Surgeon Richardson. A Sunday afternoon was selected, when the merchants had disposed of their stocks. All awnings on the side were let down and hundreds of pots were placed on the floors. In addition piles of crude sulphur were placed every few feet on the windward side. In this way we were able to use up a carload of Louisiana crude sulphur that had been donated to the Service, but which we had hitherto been unable to use, as it would not burn in pots. Sufficient concentration of gas was obtained to kill flies; so I infer that mosquitos, if there were any, were also killed.

There is an end to most mundane things and the tons of sulphur burned had its effect. The number of new cases in the district, which reached its maximum August 12, declined steadily until September 23, when no case was reported for that day, and few other cases occurred subsequently. The official estimate by Dr. Kohnke, the City Health Officer of New Orleans, was 100 cases and 20 deaths prior to the official announcement on July 22. All of these cases and deaths occurred in the "Infected District." After my own investigations I have concluded that the estimate of Dr. Kohnke is too high as regards the number of cases and too low as regards the number of deaths. My own estimate, after a fairly thorough investigation, is 60 cases and 30 deaths, all but three of the deaths occurring in the "Infected District," and these three being made up by three more occurring between the dates of July 21 and July 24, and not getting on the official report as yellow fever. The first traceable cases occurred at 1115 Gallatin street, where deaths occurred July 1, 2, and 3. Another patient was critically ill at the same time, but recovered after having black vomit. These four cases were doubtless secondary cases, the primary case occurring at least as far back as the middle of June. This house in question on Gallatin street was a barroom, and if no case of sickness was treated in the house in the middle of June, as was asserted, it is not improbable that a walking case had spent several hours at the place and infected the mosquitos. The next fatal cases, occurring but ten days later, could be tertiary infections from this or adjoining houses, or the case in early part of June had wandered about infecting other houses.

The dates of deaths of probable cases are as follows:

July	1.....	1 death	
"	2.....	1 "	
"	3.....	1 "

Totals—859 cases, 115 suspects, 175 deaths.

The tabulated suspects are those which were never confirmed as cases of yellow fever. Whenever a case was subsequently confirmed it was removed from the suspect column and added to the positive cases of the day when the original report of the case was made.

A census of the district taken by the lay inspectors gave a population of 8,500; of these people 500 stated that they had been immunized in previous epidemics. Lumping positive and suspicious cases we have a local epidemic of 1,000 cases in a population of 8,000 non-immunes, and with a mortality of 17½ per cent. The balance of the population can be regarded as protected from yellow fever by the various means instituted.

Taken by weeks the statistics show more rapidly the rise and fall of the epidemic. It is to be noted that a force of fumigators adequate to handle the newly infected houses and to begin block work was not obtained until August 18. Besides, in the early part of August many houses and over a hundred rooms of houses contained persons too seriously ill to be moved, and on an average it took at least ten days before these rooms could be entered. It was not until August 18 that the unknown foci in the district had been eliminated and fumigation performed in the rooms where the sick were in the first ten days of the month.

A better indication of the rapidity of results is shown in figures of the block in which the headquarters of the infected district were located. Forces were first concentrated in this block, which had a population of about 400, almost all Italians and non-immunes.

Three cases, two fatal, occurred in the next two weeks, but all were clearly imported ones. On or about Sptember 8 there arrived a party of twenty Italian immigrants en route from New York to a Louisiana sugar plantation, and who were consigned to a shipping agent in our block. They were unable because of quarantine to proceed further, and at my advice the agent quartered them in a lodging house nearby, which I then considered safe. They remained in this lodging house, 528 St. Philip street, for nearly three weeks before they were able to leave for the plantation. During this time not a case of illness of any kind occurred among them. They were all warned not to leave the house after nightfall and I believe this advice was obeyed. During the daytime they wandered about the streets and markets as they pleased. The previous record of this house had been seven cases, two fatal, the last case occurring August 14. The neighboring houses were as badly infected: two of the imported cases dying in adjoining houses the week previous to the arrival of this party. The worst record of a single house in the district was that of 511-515 Hospital street, in which twenty-three cases, seven fatal, occurred between the dates July 29 and August 12. Every occupant of the house was stricken and the sick were so numerous and the house so small that little preliminary fumigation could be done. After the recovery of the last case, naturally no further case occurred in the house, although it should be added that another family moved into it in the latter part of September.

In New Orleans the moving day is on October 1, and fearing that the wholesale shifting of population would be causative of further diffusion of the disease, moving was restricted by not allowing furniture to be moved into a house in our district un-

til written permission was given from our office. Then permission was not given until the house or part of the house that the family wished to move into was again fumigated. The purpose of this was twofold—to kill any infected mosquitos that might be alive at the house, and thus to prevent infection of the family, and to kill non-infected mosquitos so that in case any member of the family was in the incubative stage and would later be attacked in the house, the house itself would be then practically non-infectible territory and another focus could not be established. In addition to the families moving openly into houses at this time there were coming into their houses towards the latter part of September hundreds of Italians who had slipped away in the middle of July, and were now returning as they departed, in the night. These people brought no baggage with them, as they took none away, and they could not be detected in that way. But the sidewalks, which were practically deserted during August, were now quite different. It was an unconscious tribute to the sanitary authorities of the city that frightened people would now be returning of their own accord, two months before frost was expected. It is apropos to say that this same exodus in the middle of July had been one of the means of the wide diffusion of the disease in the city and State.

Contrary to what might be expected, in most of the infected houses there was no typical period of pause between primary and secondary cases. There were about as many cases three days after the first case as five days, ten days, or fifteen days, or any other number. In a country district where houses are far apart and the visits to each one are distinctly remembered by persons, the tracing back of an infection is not a difficult matter. However, in a badly infected area in the heart of a populous city the conditions are different. Even if the individual does not visit his neighbors, an infected *Stegomyia* has only to fly from one back door to another, only ten feet away, and if she does not leave a visiting card she often leaves pronounced evidence of her visit. However, following the primary deaths occurring between July 1 and July 21, I can in the majority of cases point out secondary cases or deaths at intervals of from thirteen to thirty days. The high degree of the infection of the district is shown by the statistics of the infected houses themselves. The 871 reported cases occurred in 355 houses. The 115 cases, reported as suspicious and never confirmed as positive, occurred in 93 houses. However, 70 of these 93 houses are already included in my list of positive infected houses. It is reasonable to suppose that most of these unconfirmed cases were genuine yellow fever of a mild type. As time progressed a larger portion of the cases in the district were called suspicious and the death rate fell among the positive cases. My belief is that the severity of the type of disease was lessened by the individuals being bitten by fewer mosquitos. In addition to the 355 known infected houses and the 25 additional suspected houses there were undoubtedly many unknown infected houses in which the infection was either wiped out during the block work, or when caught as an adjoining house. Several of the known and doubtless the unknown foci as well were barrooms and corner groceries. On Sunday and slack days these places were fumigated. Most of the saloonkeepers objected strenuously to this interference with their business on week days or on Sundays.

The vigorous sanitary measures instituted were not without considerable cost. Fifty tons of sulphur, tons of paste, paper, barrels of alcohol, and large quantities of other material were used. I estimate the cost of the two months' campaign at $15,000, two-thirds of which amount was expended for labor. However, when it is considered that about one-third of the actual cases and over one-third of the deaths in the city occurred in this district, and that a large number of the cases in the city at large were correctly attributed to infection in the French Market territory, the cost of wiping out this infected spot was cheap. When compared with its benefit to the commerce and future growth of a city of 300,000 the expense was a mere bagatelle. Besides the total fund of less than one-quarter of a million disbursed by the Service and city seems small when compared with the benefits derived from the lessons of the campaign. For instance, I was informed that after the epidemic was under control, and with the probability of its being wiped out all over the city before frost, real estate, which had been dull from time of announcement of the epidemic, became active once more, and began to change hands at prices even higher than those which had prevailed before the epidemic. The fear of such epidemics as scourged the city in 1854 and 1878 was forever removed, and New Orleans was conscious that a new era was before it.

Because the "infected district" did not in its boundaries follow ward lines, the work carried on was without the affiliation or assistance of any ward organization. However, the patience of many good citizens in their acquiescence to the seemingly harsh measures was sufficient assistance on their part, and this moral support most of them gave. But to such as did not, and valued their private comfort more than the public weal, and to those, mostly aliens, who resisted in their ignorance, the police and the courts above them presented a firm and unyielding front. Without the support of police and courts, and the intelligent and faithful work of the loyal foremen together with the rank and file of the sanitary laborers, the work could not have succeeded in this alien colony. This, after all, was one of the manifestations of the public opinion of the city.

As for myself, I feel that I am only to be congratulated that mine was the good fortune to have the first opportunity to attack with a sufficiency of men, money, and authority, an epidemic of yellow fever that had gotten a good start. Similar successful results were obtained in all of the seventeen wards of the city, and the infected district differed only in degree of infection and in that the sanitary workers had gotten an earlier start. Similar results would have been accomplished by Dr. Louis Crawford had I not been fortunate enough to return from my sick bed to my work. As it was, because of the augmented force of men, more work was done during my absence than at any similar period during my command. Then, too, the fumigation for the infected and non-infected *Stegomyia* was only one of the cogs of the great sanitary machine running under the supervision of Surgeon White. The work of oiling of cisterns and other water containers and the search for hidden sick by lay inspectors, under the direction of P. A. Surgeon Richardson; the diagnosing of these sick by medical inspectors under the supervision of Dr. M. Landry of New Orleans; the reporting of their private cases by the physicians of the city in spite of contrary desires of many of their patients; the yellow fever hospital for the reception of cases, under the management of Dr. Hamilton Jones of New Orleans; these

were all factors that contributed in various degrees to bring about successful results in the original infected district.

As my opportunities were superior for observing at close range the first large epidemic of yellow fever ever controlled, I may be excused for offering this article. Moreover, I have a further reason for putting the statistics on record, because in previous large epidemics no accurate statistics were kept or could be kept.

INTERCURRENT TYPHOID FEVER IN SURGICAL AND RENAL CASES.

By G. FRANK LYDSTON, M.D.,

CHICAGO, ILL.

PROFESSOR OF GENITOURINARY SURGERY AND SYPHILOLOGY, MEDICAL DEPARTMENT OF THE STATE UNIVERSITY OF ILLINOIS; SURGEON TO THE LAKESIDE HOSPITAL.

The importance of being continually on the alert for medical complications in cases primarily of a strictly surgical character cannot be too strongly insisted upon. I herewith append the histories of three cases, two of which illustrate the point in question, and at the same time forcibly demonstrate the necessity of the surgeon keeping in pretty close touch with at least the more common forms of disease which are supposed to be the special property of the internist. That typhoid fever occurs in the course of surgical cases, operative or otherwise, and is overlooked more frequently than is ordinarily supposed, I am firmly convinced from the experiences I am about to record.

Case I.—Woman, aged forty, with a history of severe attacks of renal colic attended by hematuria coming on at varying intervals for a period of fourteen years, was taken with a severe attack of what was described as dysentery, about a week before coming under my care. The bowel discharges were frequent, painful, and accompanied by severe tenesmus. The patient was not sure whether or not there had been any blood in the stools.

At the time of my first visit the pain had become localized in the vicitity of the right kidney. There was distinct tenderness and fullness in the loin, and anteriorly in the flank. The urine contained an abundance of both blood and pus. The pain radiated typically along the ureter and was associated with frequent and painful micturition. The quantity of urine was considerably less than normal. There were occasional chills, and the temperature varied from 101° in the morning to 102° in the evening. Patient stated that an *x*-ray examination had been made and a calculus found. It was impracticable to take a new skiagraph. I endeavored through the husband to secure the *x*-ray picture from the physician who had it in his possession, but was unable to do so, notwithstanding which I felt warranted in making a diagnosis of calculus in the pelvis of the right kidney and a calculous pyelitis with perirenal abscess. Urinary examination for tubercle bacilli was negative.

Operation was declined, so there was nothing to do but to palliate. At the end of about a week the pain had disappeared, although the condition of the urine remained practically the same. The temperature remained uniform, approximating 102° F. I noticed at this time that the patient had a slight cough, and that in blowing the nose or expelling mucus from the throat a small amount of blood was expelled. This, taken in connection with the suggestive facies, aroused my suspicions, and I had a blood examination made, which showed a typical Widal reaction. The diagnosis of typhoid being thereby established, I turned the case over to Dr. William E. Quine for medical treatment. The characteristic rose spots were discovered a few hours later, and were very plain when Dr. Quine and I first examined the case. The case ran the ordinary course of typhoid fever, but an unfortunate complication developed in the form of double parotiditis, a condition which proved exceedingly painful and exhausting.

I was asked by Dr. Quine to resume the surgical management of the case, and subsequently operated on first one parotid, and then the other, evacuating a small amount of pus and necrotic gland tissue. The operations afforded relief. The patient was apparently convalescing nicely when severe pain recurred in the kidney, with an associated recurrence of temperature. The urine, meanwhile, had been at no time perfectly clear, although it had improved considerably. Operation again was suggested, but declined. The patient subsequently suffered so severely that it was necessary to administer large doses of opiates, and finally chloroform, in order to give her relief.

Operation was finally consented to, but deferred until relatives could arrive from a distance, three or four days of valuable time being thereby lost. The last forty-eight hours before the operation the patient was compelled to take chloroform very frequently to afford relief from the frightful pain. I finally performed the operation and found the kidney extensively broken down, and the seat of three large abscess cavities connecting with a perinephritic collection of pus. In the pelvis of the kidney a moderate-sized, irregular stone was found. The patient did not react from the operation, but died of shock two hours later.

Case II.—Man, fifty-nine years of age, was referred to me for operation for an inguinal hernia of long standing and perineal section for bladder drainage. While the history was somewhat obscure, the occurrence of the hernia was dated back to childhood. The perineal section possessed no features of special interest, consisting merely of external urethrotomy, followed by drainage through the perineal wound. The hernia proved to be a very complicated affair. I found an old incarcerated omental hernia, in the midst of which, well up in the canal, was a degenerated retained testis. The folds of omentum were matted together by old inflammatory exudate, evidently from successive attacks of inflammation from one cause or another. Spread out over the hernial protrusion was the pampiniform plexus, the veins of which were enormously enlarged and very numerous. Great difficulty was experienced in freeing the sac, which was intimately adherent to the omentum. Besides this old infantile hernia, there was an oblique intestinal hernia of comparatively recent date. According to the history, this had become strangulated from time to time, and had been reduced by taxis. The operation was somewhat prolonged on account of the careful dissection necessary, and was followed by a moderate temperature, which was attributed to severe bladder irritation and an exacerbation of the cystitis which followed the operation. The bladder was exceedingly intolerant of the drainage tube, and this, combined with sleeplessness and a moderate degree of infection from the bladder and the perineal wound, seemed an all-sufficient explanation of the temperature, which ranged from 101° to 102°. The temperature varied between these limits for two weeks, then fell to a point ranging from 99° in the morning to 100½° in the evening. The patient was sitting up, the hernial wound having healed by first intention. The perineal wound, however, had not closed,

and there was still considerable cystitis. The tube had been removed. A few days later the temperature began slowly to increase, and on the twentieth day the morning and evening records showed 103°. The facies of the patient impressed me as that of typhoid. On inquiry, I found that the stools, the frequency of which had alone been recorded on the history sheet, had not only been moderately frequent, but thin in consistency almost from the first. The Widal reaction was typical of typhoid, and the patient ran the usual course of a typhoid of moderate severity.

Case III.—I was asked by my friend, Dr. Johnstone, of the Lakeside Hospital, to see in consultation with him one of the nurses, a young woman of twenty-three or twenty-four years of age, who was suffering from a severe attack of acute nephritis. The urine showed fully 50 per cent. of albumin by bulk; there was marked cardiac weakness, and edema of the lower extremities. The urine, however, was secreted in fair amount, and showed no marked decrease in solids. There was severe pain throughout the abdomen and back, which feature of the case was responsible for my being called in counsel. The nephritis had followed what was taken to be an attack of la grippe, and was apparently a typical one of toxemic nephritis, such as is frequently met with as a sequel of grippe. The case progressed indifferently well for some days. There was apparently no necessity for further counsel. I was, however, in the habit of calling to see the patient casually in the course of my visits to the hospital. On one of these casual visits I was struck by the peculiar facies of the patient, which was decidedly suggestive of typhoid. I suggested to Dr. Johnstone the advisability of a Widal test, and much to the surprise of all concerned typhoid was demonstrated, the case subsequently running a typical course of that disease, the patient recovering.

The discovery of typhoid fever in no wise changed my opinion as to the etiology of the nephritis. The case was evidently one, not of typhoid with a nephritic complication, but a nephritis with a complicating typhoid.

My experience with the foregoing cases has caused me to speculate somewhat as to the probable frequency with which intercurrent typhoid fever is overlooked by the medical or surgical attendant upon cases of a distinctly surgical character.

100 State Street

NUTRITION A FACTOR IN TOOTH DEVELOPMENT.

By William J. Lederer, D.D.S.,

New York.

Lecturer at the New York College of Dental and Oral Surgery.

It is a well-known fact that lesions of peripheral organs can often be linked with systemic disease, and in the course of the progress of medicine many symptoms that were formerly treated as local disease have been recognized as being produced by systemic conditions. In this progress of the recognition of disease, its symptomatology, etiology, and treatment, a factor has been overlooked, or rather its various conditions and relations to systemic disease have not been allotted the prominence in symptomatology it actually deserves. This factor is the condition of the teeth and the relationship these organs may bear to systemic disease.

Dentistry, as an individual calling has within the last twenty five years made greater strides than perhaps any other branch of the art of healing, and from the mere mechanical replacing of lost organs for the sake of cosmetic effect, it has developed into dental and oral surgery, with a symptomatology and materia medica of its own.

From year to year fewer teeth are sacrificed, oral conditions are better recognized and more successfully treated from the oral specialist's point of view, but the actual coherence of certain dental, oral, and systemic conditions has not been as fully recognized as is necessary to obtain perfect results from both the medical and dental point of view.

That the teeth are affected by systemic conditions is true, for any pathological condition that will alter the metabolism of the body is bound to bring about changes here as well as anywhere else, as the teeth are part and parcel of the human economy, and receive their blood, lymph, and nerve supply from the same sources as the other parts of the body. Were it not so, how can we account for the variations in the dental organs of different temperaments, as one finds variations in cranial contour, general framework, muscular development, or quality of the voice? Thus the long, fine, bluish tooth is found in subjects with a prominent, not broad, but expansive chest; and the rather broad, unshapely, opaque, and muddy-colored teeth in subjects with a large chest, though lacking in expansive power, showing that all factors exercising influences upon the system at large will also reflect upon the teeth.

Hutchinson long ago recognized the peculiar appearance of the teeth in inherited syphilis, and the atrophic changes affecting the teeth after diseases like typhoid fever, rickets, and sometimes scarlatina and measles, are also well enough known. Odontalgia in a sound tooth, as the result of some distal irritation, so often met with in pregnant women, hardly needs any mention. Still all these dental affections were at some time considered local lesions, and only in course of time was their true etiology recognized. Thus there are conditions which the dentist meets to-day, and often hopelessly tries to combat with local treatment, which undoubtedly will some day be recognized as associated with and caused by some systemic trouble.

Pyorrhea alveolaris is a condition about which many theories have been advanced. What is it? A condition in which there is a hyperemic, flabby condition of the gums, a purulent discharge from the alveoli with the formation of distinct pus pockets, loosening of the teeth, and destruction of the alveolar walls. The usual treatment consists in the removal of all deposits and the sterilization of the pockets and alveoli and the local application of stimulants and counterirritants, to induce a return to the normal. The success attending the treatment of the disease is limited because the actual cause is not always established. The deposits which so frequently are looked upon as the actual cause of the trouble are but exciting causes. Miller and other investigators attempted to isolate a microorganism specific to the disease, but failed. The condition is frequently associated with uric acid diathesis and diabetes mellitus. It is a local manifestation of some perverted function present in these diseases.

Success in the treatment of oral diseases cannot be obtained unless the etiology of these conditions is thoroughly understood. This offers a broad field for investigation to both medical and dental men, and those who succeed in clearing the fog will not only be benefactors to suffering humanity, but they will be disciples of Æsculapius in the true sense of the word; not only will they be healers, but they will also be preventers of disease. The greatest triumph

of medicine is not the curing, but the prevention of disease.

The various conditions affecting the teeth can be classified as affecting the dental organs during certain periods of life, namely:

1. Those conditions bearing influence upon the teeth during intrauterine life; this would be the period beginning with the first appearance of the epithelial inflection in the embryonal jaw (thirty-fourth to fortieth day) and ending at birth, the prenatal period.

2. Those conditions affecting the denture during infancy and childhood, *i.e.* during the period beginning at parturition and ending with the eruption of the first permanent tooth.

3. Those conditions affecting the teeth from the time of the eruption of the first permanent tooth till death or such time as the teeth are lost.

It is evident that in the first class, the conditions affecting tooth development are factors conveyed by the fetal circulation and are traceable to the mother. Any condition affecting the maternal blood is liable to have a reaction upon the embryo and fetus, and consequently modify tooth development. It therefore follows that the health of the mother during gestation is an important factor conducing to normal tooth development, and any pathological conditions present must be considered and corrected. All conditions which will lower the vitality of the mother are bound to affect the child *in utero* in some way, and the developing dental organs being part and parcel thereof, receiving blood supply from the same source, will consequently be modified if there be any aberration from the normal in the blood, chemical or physical.

The first indication of the future denture is observed about the thirty-fifth to the fortieth day of intrauterine life, when there appears an ingrowth of epithelium extending along the whole length of the jaw, rapidly extending into the mesoblastic tissue. This growth of epithelium assumes the shape of a flask, that is, it broadens downwards and is rounded off. This is known as the enamel organ; soon there appears a cell proliferation in the mesoblastic tissue, pushing its way into the bottom of the flask, crowding into the same, so that the epithelial growth covers the mesoblastic tissue like a cap. This mesoblastic cell invasion is known as the dentine papilla, as it forms the future dentine, as the enamel organ is the precursor of the outer covering of the crown of the tooth. There are now two distinct structures, an epithelial body (enamel organ) and a mesoblastic body (dentine papilla). The cells of the enamel organ now undergo a series of differentiations: the innermost layer is arranged as columnar epithelium, and is called the enameloblastic or enamel-forming layer; the cells of the outer wall remain cuboidal. The cells between the two become much distended, and have on account of their appearance been termed the stellate reticulum. The enclosed dentine papilla also undergoes cell changes, and there appears a peripheral layer of columnar cells which become dentine-forming cells, termed odontoblasts. By the time that calcification begins there is formed a capsule-like investment surrounding both the enamel and dentine organs. When this sacculus is fully formed, it is made up of an outer and inner wall, both very vascular. The outer wall becomes the dental periosteum, while in the inner wall, especially in the vicinity of the roots, osteoblasts appear and are calcified into cementum. By the time the crowns of the teeth are formed each tooth is incased in a crypt of bone, developed around, but at some distance from it; the crypt is open towards the gum, shielded by fibrous tissue. The permanent teeth are contained in the same crypt as the temporary teeth, but later become separated from them by a bony septum. The first appearance of epithelial inflection, according to Tomes, takes place about the seventh week of intrauterine life. The dentine papilla grows into the enamel organ about the tenth week. At eleven and a half weeks all the temporary tooth germs are formed. Having formed, so to speak, the organic network of the teeth, at about the twentieth week calcification of the teeth begins. Calcification, according to Sudduth, is that process by which organic tissues become hardened by deposition of lime salts in their intercellular substance, as exemplified in the formation of bones and teeth. The intercellular substance in organic tissues is fluid, and into this fluid particles of lime salts are deposited in regular systems, after the several forms of calcified tissues. This arrangement is superintended by specialized cells for each particular structure-osteoblasts for bone, odontoblasts for dentine, ameloblasts for enamel, cementoblasts for cementum. A great deal more could be said about tooth development and calcification, but for a careful study I would refer the reader to special works on this subject. The above will suffice for the present if it is but borne in mind that the various osteogenetic cells derive their supply from the blood.

To obtain a normal organism, three factors are essential: (1) Normal formative organs; (2) normal nutritive fluid; (3) normal physiological function. This, of course, also pertains to the dental structures. There must be normal formative organs, *i.e.* there must obtain a normal enamel organ and a normal dentine papilla—in short, there must be a normal tooth germ. The second essential factor is a normal nutritive medium, which is the blood—and there must obtain normal physiological function, which in turn is dependent upon the normal nutritive fluid.

Abnormal formative organs may be rendered so by (1) degeneration due to lack of use, producing atrophy; (2) to heredity; (3) to accident; (4) disease may also produce abnormal formative organs, as it is said that the pits and ulcer-like marks in the enamel of defective teeth are the sequence of ulcerous points upon the tooth follicle where formation was impeded during an eruptive fever.

The second factor—normal nutritive fluid (and that means blood) is even more important than a perfect formative organ, as upon the nutritive fluid depends the health of the future organ. An abnormal formative organ, properly nourished and developed, becomes an ill-shaped, but still a useful, healthful organism; whereas no matter how perfect the formative organ may be, when nourished by an unphysiological nutritive fluid it is bound to develop into an abnormal, pathological organism. To obtain normal formative organs is beyond our control. Excepting to utilize the precursors or parent organs so that no retrogression in reproduction will result.

Professor Talbot, in a masterly essay on "Interstitial Gingivitis" (Rigg's disease), speaks of the natural predisposition of the oval structures to disease, and says: "Because of man's advance in evolution, and because of the local degeneracies thereon resultant, through the law of economy of growth whereby one structure is sacrificed for the benefit of the organism as a whole, the face, teeth, gums, alveolar process, and peridental membrane (being variable structures) are predisposed to disease in their very order of evolution.

"The jaws are growing smaller because large ones are not required. The structures are changing shape to adapt themselves to the new environment.

Thus, instead of large broad jaws with low vaults, short broad alveolar processes in plenty of blood supply and vitality to resist mastication; teeth short with large bell crowns to give plenty of room between the roots for considerable thickness of the alveolar process for the nourishment of the peridental membrane and support and protection of the gum tissue—small, narrow jaws occur with apparently high vaults; long, slender and thin alveolar processes, which are not used in mastication with sufficient force to carry blood for the nourishment of the tissues. The teeth are changing their shape, causing the roots to come closer together, and thus lessening the area of the alveolar process.

"Since man has not adjusted himself to his new environment, the face and jaws may be said to be transitory structures. The teeth in some of the lower vertebrates develop continuously. That is, they come into place, possess large foraminas, serve their purpose, are shed and new teeth take their place. This is continued throughout the life of the animal; unlike this man has but two sets. The first teeth erupt; the alveolar process builds itself about the teeth to hold them in place. These are shed, the alveolar process absorbs, the second set appear, and the alveolar process builds itself about them to hold them in place. When the second set are lost the alveolar process is again absorbed.

"I have demonstrated this absorption many times upon dogs. Whether it is due to an erupting tooth, the movement of teeth by wedging, correcting irregularities, after extraction othosteohialacia, it is invariably an inflammatory process. The building up and tearing down of the alveolar process also demonstrates it a transitory structure. This, together with the evolution of the face, makes the alveolar process doubly transitory. So sensitive is the alveolar process to inflammation and absorption, the slightest irritation, whether local or constitutional, will set the osteoblasts at work.

"The teeth are virtually foreign bodies in the mouth. The tendency is to shed the second set as a result of atavism. The foramina are nearly closed; hence the blood pressure in the pulp is *nil*. The blood-vessels extend through the alveolar process and peridental membrane and stop short. Nourishment ceases, the teeth are like ivory pegs set in the jaws. In the study of the evolution of the pulp, their attachment and the use of the teeth in the scale of evolution must appeal to every scientist that the law of economy of growth resulting in degeneracy is very apparent. The blood-vessels and new tissues, therefore, at this locality, may be called terminal structures. These blood-vessels do not run straight through the bone, but ramify in all directions forming loofs or plexuses and are intimately connected with the peridental membrane and gum margin."

If it is not in our power to determine normal formative organs, we can, however, at least partially create and maintain a normal nutritive medium—normal blood. What is meant by normal blood? Blood which contains all those substances that are necessary for the maintenance and growth of the organism in physiological, *i.e.* assimilable, form, and in physiological quantities. Inasmuch as dental development begins before the second month of gestation is reached, it is evident that dental prophylaxis should be installed before calcification commences (about the twentieth week), as it is not within our reach to direct the formation of normal developmental organs. We can, however, by dietary and hygienic measures and proper medication, alter any abnormal condition of the mother's blood so as to bring about or create a normal blood condition, excepting in some forms of chronic disease. If the blood condition of the mother be rendered normal, it is safe to assume (granting that no organic lesion or chronic disease be present) that embryological and fetal development will be normal, and consequently the resulting denture will be healthy. This was recognized some time ago, and caused dental prophylaxis to take a new direction. The dentist, instead of prescribing calcium compounds, when his patient complained of soft teeth, advised his pregnant patients—in order to insure the child *in utero* a full dose of calcium salts—to take lime salts internally during the whole period of gestation. With what results?

Some years ago Professor Sands took up this line of work, with reference to the general osseous system, and Dr. Hodson collaborated with Dr. Sands in taking up the dental phase—and failed. Other men carried on similar experiments (feeding pregnant women on calcium salts), and when the term of delivery came a number of craniotomies had to be performed that might have been avoided. Harder or more resistant teeth were, however, not produced. In some cases, where labor was normal, the children later showed defective teeth, and children whose mothers were not subjected to a "hypercalcified diet" developed normal healthy teeth. How is this to be accounted for? The necessary material, calcium, was introduced into the system at a period when it was needed, and still the tissues, though demanding it, did not accept it. Where did it go to? In the cases where calcium was given the feces showed an increased amount of calcium, indicating that the body passed it off, and that it had not been offered to the tissues in properly assimilable form. Nature will not be commanded to "take this or take that!" She makes her demands, and then chooses. It is not only a question of alimentation, but a question of assimilation.

But how is the problem to be solved? How can it be brought about that the nutritive medium, the blood, shall be normal, that it shall contain the precious calcium salts and other earthy ingredients, which are necessary for calcification, in such quantities and in such form that the tissues will accept them? Not by loading the stomach with marble dust and apatite, but by offering the system the necessary ingredients in such shape as nature gives them, namely, as food; then all the calcium salts that are required for calcification will be taken up by the blood, distributed to and appropriated by the tissues. If food alone will insure proper dental development and calcification, how can it be accounted for that so many individuals develop defective teeth? A number of reasons can be brought to account for this: (1) Irrational mode of living on the part of the mother during gestation; (2) hereditary influences; (3) diseases during infancy.

It is not necessary to open text-books and to quote authorities on obstetrics, but common sense should tell every pregnant woman that her systematic condition is an altered one, and that her mode of living during gestation must be different from that before conception. She must live in such manner as to be able to satisfy the physiological demands of the embryo and the fetus. What does the child *in utero* demand? Proper food, *i.e.* physiological blood, which is obtained by proper diet on the part of the mother; diet that is nourishing and easily digested; proper aeration of the blood, which demands plenty of oxygen and sunshine; proper exercise.

It has been demonstrated that children born in the country are not so frequently afflicted with

rickets as children born in thickly-populated districts.

There are, of course, many other points that an expectant mother must consider, as dress, hygiene, regular habits, etc., but the foodstuffs are the points at issue in this paper.

What are the foods that are conducive to proper dental development? Recognizing the fact that the teeth demand calcium salts and other earthy ingredients, foodstuffs containing these ingredients in assimilable form are the ones required.

Von Winkel, in his Maternal Clinic in Munich describes a dietary as follows: Breakfast—¼ liter milk, one roll. Noon—¼ liter of soup, 150 gm. of beef without bones, ¼ liter vegetables or pastry (not fat), ¼ liter beer.

All the patients at this institution, unless bedridden, are compelled to do light work about the building, which gives them moderate exercise, thus stimulating all bodily functions. Regular habits are insisted upon—personal hygiene and cleanliness need not be mentioned—and the results are gratifying. Many a woman who would not live past delivery, and many a one who would give birth to a sickly child, is delivered of a normally developed, healthy offspring, and both mother and babe leave the institution hale and hearty. What do our modern mothers and ladies do? Do they modify their dress, habits, and mode of living during gestation? Do they sacrifice their rarebits and goose-liver patties? Do they give up their social appointments, to be able to retire early, so as to insure plenty of sound sleep? Do they attempt to create physiological conditions within their own bodies, to pave the way for a healthy offspring? No; they do not take any notice of that child to come, may even attempt to hide its presence by lacing the expanding abdomen, throw themselves into the social tide to forget—and the unfortunate offspring often has to pay for its mother's folly.

Milk is the most important of all animal foodstuffs, containing all the elements necessary for the maintenance of life, and thus constituting a complete food. It contains all the four classes of food principles, namely, proteins, fats, carbohydrates, and salts. If pregnant women would drink more milk and substitute this perfect food for some of the "impossible epicurian artifices," lead a proper life, and not absolutely ignore nature—by sacrificing some of their late wine suppers and gay all-night parties—this would not only insure their own health, but they would be able to give birth to a child in good general health and with a good denture.

The above-mentioned dietary is only one of one practitioner of note and can be substituted by others: the main point is a simple mixed diet in accordance with the patient's individual wants. It shows that no excess of calcium salts is necessary for proper embryonic and fetal development, but a simple and wholesome diet and physiological mode of living will do more than dietetic feats. Proper food and a rational mode of living on part of the mother create natural conditions for the embryo and fetus. At the time of birth all the crowns of the temporary teeth are calcified and the cusps of the six-year molars are beginning to harden. The last of the teeth to erupt are the third molars; these are not thoroughly calcified until about the twenty-first year of life and often later. We therefore say, roughly speaking, that the crowns of the temporary teeth calcify *in utero*, and the roots of the temporary and the permanent teeth (excepting the cusps of the six-year molars) after birth.

Therefore, about twenty-two years of human life is necessary to form and calcify the denture, and therefore many and long are the influences which may affect the development and growth of the organs of mastication. Normal blood condition of the mother, normal metabolism, that is anabolism and catabolism physiologically balanced, will insure for the offspring a sound set of temporary teeth. The calcification of the temporary teeth does not begin until after birth and the nutrition of the child becomes a factor to reckon with in the calcification of the permanent teeth.

A great deal has been written and said about infant feeding, a whole literature abounds on the nutrition of infants and children; physicians, chemists, and physiologists have devised methods, systems, and dietaries to provide the newborn with materials known as food to replace those substances which are utilized by the body in the performance of those physiological functions which constitute life, in cases in which nourishment as nature provides it, namely mother's milk, has been denied or so altered by disease that it fails to fill its want. Nothing as yet has been found which will absolutely and perfectly replace that source which God gave to every new being to draw its nourishment from. The nearest approaching to mother's milk is cow's milk, but even this does not fully replace the secretion of the maternal breast (as will be seen later on), for God intended it for calves and not for babies—and God never makes a mistake. Wherever it is impossible to obtain mother's milk, we have, of course, to employ those materials which most nearly approximate mother's milk, but, unfortunately, in these days many a child is denied the only perfect food (mother's milk) in consequence not of ignorance on the part of the mother but of a tendency to shirk those sacred duties which a mother assumes when she gives birth to a child. This tendency to substitute artificial food for mother's milk not only imposes a tax upon the infantile organism during digestion, which the body is not subjected to if mother's milk is given, but it actually creates conditions which are not normal, affecting the whole system, not barring calcifying teeth. It is true cow's milk contains all the ingredients of a perfect food, namely carbohydrates, proteids, fat, salts, and water, but not in the same proportion and degree of digestibility of mother's milk. We have contained in cow's milk the precious earthy salts so necessary for calcification, but its other ingredients make it more difficult to digest and its assimilation is not as perfect as that of mother's milk.

The question whether a child shall be strong and robust or a weakling is often decided by its food during the first three months. An infant spends most of its time sleeping and growing and at this time the muscular effort is not great. It therefore follows that the diet of an infant should contain relatively more of the tissue builders (proteids and mineral matters) and relatively less of the energy producers (carbohydrates) than one finds in the food of an adult. Proteids are furnished by the casein and other albuminoids present in women's and cows' milk, in the white of egg, gluten of wheat, fiber of muscle, etc. It is the great difficulty in the digestibility of proteids that causes the principal troubles in the substitution of cow's milk for woman's milk.

	Woman's Milk.	Cow's Milk
Water	89.6	87.7
Casein	1.4	3.0
Albumin	0.6	0.4
Fat	3.1	3.7
Sugar	5.0	4.5
Ash	0.3	0.7

Salts contained in:	Woman's Milk.	Cow's Milk
Natrium chloride	1.35	0.902
Calcium chloride	0.70	0.870
Calcium phosphate	2.50	1.477
Natrium phosphate	0.40	
Magnesium phosphate	0.50	0.336
Sodium carbonate		
Fluoride of calcium	a trace	
Potassium citrate		0.495
Magnesium citrate		0.367
Calcium citrate		2.133
Iron phosphate	0.01	

According to von Bibra:

	Dentine.	Enamel.
Calcium phosphate and fluoride	66.72	89.82
Calcium carbonate	3.30	4.32
Magnesium phosphate	1.18	1.34
Other salts	0.83	0.88
Fat and organic matter	28.01	3.59

Dr. Koplik, in his work on diseases of infancy and childhood, in speaking of the principles underlying the process of nutrition, says of the mineral salts as follows: "The skeleton in the first year increases fully 2.2 pounds or one kilo in weight and the earthy phosphate being an important element in the composition of the bones, 3.5 gm. of phosphate of calcium are used every week during the first year by the skeleton. This demand of the skeleton for lime salts is met by the food of the infant—the milk—much better and in a more assimilable state than by any food taken by the adult subject." A fact which contraindicates the giving of starchy foods during the first year of life. "The muscles also need a certain amount of lime salts, and a dearth of mineral salts becomes evident much more quickly in the infant and child than it does in the adults. We see this exemplified in artificially fed infants, whose food (cow's milk) is not as well assimilated as is the mother's milk by the naturally fed infant. Whereas 800 c.c. of mother's milk contains ½ gm. of potassium phosphate, 0.2 gm. of lime phosphate, 0.6 of sodium chloride, and 2.5 mgm. of iron, and these are completely assimilated by the infant; the same salts in cow's milk are excreted to a great part, rachitis and disturbances of nutrition of the bones are very common in artificially fed infants."

Foerster reports the case of an infant four months old taking 1,215 c.c. of cow's milk, who excreted 75 per cent. of calcium salts in the feces. If the osseous system is thus affected it stands to reason that the dental organs do not escape.

Dr. Koplik also states that metabolism in the bottle-fed infant varies from that of the nurseling at the breast, that according to Rubner and Hebner the artificially fed infant needs a greater amount of food, as more energy is required by the body to compensate for the extra work called for by the intestines in the digestion of cow's milk. It must be borne in mind that the utilization of cow's milk by the infant is not perfect for the following differences between breast-fed and bottle-fed infants are apparent: (1) The increase of weight is irregular in the bottle-fed infant as compared to the regular increase in the breast fed infant. (2) The daily fluctuations of temperature in the bottle-fed child are irregular as compared with the fluctuations in the breast-fed infant. (3) The bottle-fed infant as a rule is an anemic child; the breast-fed infant on the contrary. (4) The bottle-fed infant is rachitic even from birth; it is more susceptible to infection, less resistant to the inroads of disease. The bottle-fed child, notwithstanding the utilization of the calories of cow's milk, is deprived of the enzymes and alexins.

Enzymes are the soluble ferments in human milk, the most important of which is amylase, capable of converting starch into sugar as ptyalin in the saliva. Amylase is destroyed by heat and human milk heated above a certain temperature loses its amylolytic properties. Amylase is not found in either cows' or sheep's milk, though it is present in a less degree in dog's and ass's milk. Other ferments have been isolated from human milk which is capable of splitting monobutyrin into butyric acid and glycerin, also a ferment splitting salol into phenol and salicylic acid, and another substance capable of coagulating fibrin. These substances, excepting lipase in small quantities, are not present in cow's milk. Alexins are substances bactericidal and globulicidal in character, and Moro has shown that the serum of the blood of the breast-fed infant is more bactericidal than the serum of the blood of the infant fed on cow's milk.

In Japan, where women have a remarkable abundance of milk and give their children no other food during the first year, rachitis is never seen. This plainly shows that the character of the food which an infant ingests affects its growth and development, just as the health and nutrition of a mother exert their influences upon the embryo and fetus. Most infantile diseases occur during the first year of life and are more frequently caused by faulty metabolism due to the rational feeding than by any other factor. Many children survive, but there is laid in the system the foundation for life-long disturbances and unphysiological development which of course also is bound to affect the developing and calcifying dental organs, and it is here where the cause for so-called "soft teeth" is to be looked for. A remedy for such a condition does not exist, as tooth substance once calcified cannot be made to become more compact, as dental structure after calcification is not vascular. A bone that is fractured will have its break unite by the formation of callus and the secondary deposit of lime salts, obtained from the blood streams. A tooth fracture will not unite, as the structure is void of vascularity; were it otherwise, the filling of teeth would be unnecessary as nature would regenerate the tissues destroyed by dental caries.

The prevention, therefore, must be the treatment. Patients should be instructed accordingly and the dental specialist can do missionary work of inestimable value. The great mistakes so frequently made in infant feeding are the substitution of cow's milk for maternal feeding where mother's milk is obtainable, and also the too early ingestion of carbohydrates and other foodstuff that have no place in an infant's dietary. Opinions differ as to the period when young children should be given other food than milk; however, the consensus of opinion points to the fact that no solid food of any kind should be given prior to the eruption of the temporary teeth. Milk (maternal till about the eighth month, unless weaning becomes necessary through disease on part of the mother at an earlier period; good cow's milk after that) should be the principal food for eighteen months. Starchy food should be withheld for about a year. Nutrition is the basis of all development, and if this important function is supervised according to a common-sense physiological regimen the result will be a normally developed organism. It means a healthy body, a sound mind, and good teeth. Therefore nutrition is a very important factor in tooth development. Were it not so we would not obtain the abnormalities of tooth development and eruption following diseases of nutrition, as scurvy, rickets, marasmus, etc.

150 East Seventy fourth Street.

PHTHISIOTHERAPY BY MEANS OF EMULSION BACILLI (KOCH).

By WILLIAM MEYER, A.B., M.D.,

WEST HOBOKEN, N. J.

The adverse criticisms of tuberculin which we encounter frequently in journals and society discussions should be based on a more conservative and careful investigation on the part of our opponents. This conclusion was reached by me through my own experience with both the old tuberculin (for diagnostic purposes mainly) and the new tuberculin (emulsion bacilli, used as a curative agent), and strengthened by the experience of German and French physicians and, in this country, of Drs. Trudeau, Brown, Pogue, and others. Even if the results are not entirely satisfactory and in spite of the fact that not enough time has elapsed to assure us of the permanency of the effects obtained, yet the curative properties of tuberculin are unquestionable. There can be no doubt as to the diagnostic value of tuberculin in cases in which the physical signs are practically absent or cannot be detected.

In presenting these 25 cases for consideration I wish to emphasize that no other remedy but tuberculin was employed. A few rules were instituted, but their value is doubtful, when we consider that almost all of these patients were working while under treatment. Even the few rules given could not be followed persistently and faithfully, as the nature of work of these patients will demonstrate. However, some rules had to be adhered to under all and any circumstances, in order to assure success, especially keeping a record of temperature, cough, hemorrhage if any, pain, appetite, bowels, sputum, and weight, with a few additional minor details. These cases were treated during the years 1905, 1906, and the early part of 1907. It is evident that the time elapsed gives us no assurance of the permanency of the effect, yet the results obtained justify the use of tuberculin and encourage us to further investigate.

Fatalities have not occurred, nor any relapses so far. I have selected those 25 out of a total of 30 cases, three patients having been dismissed for irregularity in taking the treatment and two having gone to Europe to continue there the same treatment. At present I have 18 cases under treatment and all are getting on nicely.

The Opsonic Index.—When we take a standard culture of tubercle bacilli and mix with the individual's blood, if we find that a large number or all of the germs are taken up by the leucocytes, *i.e.* if we notice active phagocytosis, the opsonic power of the blood is said to be on the increase and at such time tuberculin is given with the greatest advantage. Phagocytosis is, as a rule, low in tuberculous subjects, but it has been observed that this power is increased under cautious administration of tuberculin. I have not had enough experience with this method to give any definite opinion at present, but I am rather inclined to be hopeful as to its practical value. My personal experience covers only four cases up to date.

In a few cases I used the old tuberculin, which is borne less easily, in my opinion, than the emulsion, but at times it may be advisable, when the old tuberculin is not borne well, to use Koch's T. R. in an initial dose of 0.001 mgm., gradually increased to 0.1 mgm., and at this stage to go back to the old tuberculin, which is now borne better, as a rule, and gives better results. At present I use the emulsion for treatment only and the old tuberculin for diagnosis, but at times I also use the emulsion for diagnosis as well.

In the present 25 cases the emulsion has been the remedy par excellence, with the following restrictions and regulations: Patients must go to bed at an early hour, keep all windows open during sleep. When practicable they should sleep out of doors, but in a city this is almost impossible. Each patient hands me every week his record, which shows: Fever, cough, night-sweats, sputum, appetite, bowels, etc. A sponge bath is taken morning and night (cold water). Overwork, worry, etc., must, if possible, be avoided. The expectorated matter is placed in a paper cup and burnt at the first opportunity, or a porcelain cuspidor with a 5 per cent. solution of carbolic acid is made use of. The patient is told that the sputum is the means by which the disease is perpetuated, if not taken care of in the proper way. The patient must rinse mouth and nose with a 20 per cent. boric acid solution after eating and on rising, as well as on retiring. All unnecessary coughing should be suppressed. With the obedience to these rules I assure the patient that soon an amelioration will follow.

Before the injection is made I take the temperature and the pulse myself, and again from twelve to twenty-four hours afterwards. The average duration of the treatment is from five to seven months, with occasional exceptions.

Patients who persistently disobey these rules are excluded from the treatment. The initial dose of the emulsion is 0.0005 mgm., slowly increased to 5 and at times to 20 mgm.; the latter is given rarely. Injections are made on the average once a week, in a few cases twice a week for one or two months, then bi-weekly until the cure is completed (five to seven months). Some patients reach a dose of 1 to 2 mgm. only as the maximum dose in their case. If possible I avoid all reactions and I succeed in the majority of cases by the above doses. The weight, pulse, temperature, and general condition form the guide to the dosage.

The climatologist claims, and justly, that he obtains the same results as presented here, but no one can claim that any single remedy has brought about similar results as tuberculin did in these cases, for hygiene and diet, etc., play only a minor rôle in these cases. The cure was obtained under unfavorable conditions in the majority of cases, as will be seen in the table under the heading "Post-Discharge History" and "Occupation." All the patients, with one or two exceptions, were working while they took the treatment.

I have described the mode of examination and the establishment of an early diagnosis in an article in the MEDICAL RECORD of February 23, 1907, under the caption "Koch's Emulsion of Bacilli in the Diagnosis of Incipient Thoracic Tuberculosis."

Here it may not be amiss to recount a few observations made while using tuberculin. In ten different families in which one or the other member was affected with tuberculosis I found that a certain number of the rest of the family would react on the use of tuberculin, without having any visible symptoms of tuberculosis. I make mention of one boy in particular, seen by Dr. Brown, Saranac Lake, who could not find any pulmonaray trouble at the time except a slight depression under the right clavicle. In the course of two months, however, this boy developed râles and other positive symptoms. His brother had phthisis a number of months before. This experience I made in ten different families, and while some of the persons have not yet

Note. + = present or positive. — = negative or absent.

developed tuberculosis I am convinced that they are affected with it, and sooner or later will show it, unless the proper treatment is given. In these cases I found further that the reaction lasted from three to six days and very severely. In my opinion all closed cases, that is, without cough or other means to rid themselves of the germ, react more severely than the open cases.

The cases described here are divided into three classes, or groups: (1) Disease of moderate severity, patients having made a climate cure previously, but relapsed. (2) Cases of moderate involvement, with no previous treatment. (3) Cases of very little involvement, mostly apical and one-sided; in all members of this class the diagnosis was made by tuberculin, but they showed other symptoms at the same time, some having bacilli in the sputum.

The classes will be found tabulated in the three preceding columns.

In conclusion it may be said that these cases would indicate that:

1. An early diagnosis gives the greatest assurance of an early permanent cure (tuberculin being the means of such diagnosis).

2. The selection of cases has a direct bearing on the results; far advanced cases are generally hopeless and second-stage cases doubtful.

3. A cure is possible by means of tuberculin, but the permanency of such cure is *sub judice* at present.

4. The dose is to be guarded in order to avoid reaction of a severe type and the intervals between the injections should be regulated according to reaction.

5. No ill-effects have followed large doses, even in the beginning of the treatment; but it is advisable to give small doses, since the larger doses may cause symptoms which alarm both patient and physician.

6. In fever cases very minute doses have a tendency to reduce temperature; three of the twenty-five cases have acted that way.

7. Bacilli usually increase in number at first, and cough may be more severe for a time, but the improvement is early and rapid.

8. Under tuberculin the weight increases and the general condition improves, the symptoms disappear, and the patient feels in every respect better; this naturally pertains only to certain well-chosen cases.

9. These observations have conclusively shown that patients while remaining at home and at work can take the tuberculin treatment and receive a great deal of benefit from it.

I am indebted to Dr. L. Brown of Saranac Lake for several valuable suggestions in the preparation of this article, and take this opportunity to express my thanks for his kindness.

416 Clinton Avenue.

MORPHINISM.*

By CHARLES J. DOUGLAS, M.D.,

DORCHESTER, MASS.

Morphine, alcohol, and cocaine should be given preeminence among the drugs that enslave. There are other enslaving drugs, but they are not as commonly used nor as serious in their effects. Of these three, morphine is the most tenacious and exacting in its bondage, and escape from it is practically impossible without medical aid. Morphinism knows no periods of total abstinence, as is often the case with alcoholism, but every day the patient must have his regular allowance of the drug or suffer the most intense torture. The alcoholic will often have periods of weeks or months, during which time he is not only free from all thoughts of drink, but is sure that he will have no more trouble from that source. But the morphine habitué has no such experience. He is in perpetual slavery, without the intermission of a single day. The baneful effects of this drug are felt throughout the system. Almost every organ in the body is affected in some way by its habitual and long-continued use. But the most important and the most

*Read before the American Medical Society for the Study of Alcohol and Narcotics, at Atlantic City, June 5, 1907.

serious of these symptoms are those relating to the brain. The mental processes often become so changed, and the judgment so warped, that to a great extent another personality is developed. Morphinism in this stage should be classed as a mental disease.

Morphine patients occasionally use other drugs at the same time. The combination of morphine and cocaine is perhaps as common as any. This is often brought about by an effort to overcome the morphine addiction by the use of cocaine. The result of such treatment is always failure, and usually the patient finishes with two drug addictions instead of one. When alcoholics acquire the morphine habit, the two addictions sometimes continue synchronously, but often morphinism completely takes the place of alcoholism, and the last state of the man is worse than the first.

Unlike alcoholism, the morphine addiction is not a social habit, and consequently its causes must be looked for elsewhere. In a large majority of cases the habitual use of morphine begins with its employment for therapeutic purposes. Pain or discomfort of some sort is the usual cause for the administration of the initial doses.

Morphinism is undoubtedly on the increase. During the last two or three years I have especially noted that many are acquiring this habit through an effort to overcome the after-effects of excessive drinking. The theory is being passed from one to another among drinking men that the proper way to relieve the symptoms that follow a spree is to take a dose of morphine, and its use for this purpose is increasing yearly. The self-administration of this drug for any purpose usually results sooner or later in the fastening of the morphine addiction upon the patient. The use of morphine for "sobering up" purposes is an evil that is assuming serious proportions. Morphine addiction can, of course, be acquired by anyone, yet it seems to be more prevalent among people who are above the average in intelligence and social position. Both men and women of the better class are found among the victims of this treacherous drug. It is a curious fact that many physicians are addicted to it, and the self-prescribing of morphine is just as dangerous for medical men as for others.

There are few chronic diseases that are more surely curable than morphinism. But it cannot be cured at the patient's home, except under extraordinary conditions, with trained nurses day and night, and with a physician in attendance most of the time. At a good sanatorium, however, with proper care and treatment, it is entirely curable. The successful treatment of morphinism being essentially institutional, it is important that the right sort of an institution be selected. There are many sanatoria throughout the United States in which drug addictions are rationally and successfully treated. But there are others that make claims to miraculous cures by means of secret nostrums, whose methods cannot be approved. Physicians usually know the reputable institutions in their respective communities, and can advise their patients intelligently. But for some reason patients often decide the matter without consulting their family physician, and thus are liable to fall into the hands of charlatans and quacks.

The methods of treating morphinism may be divided into three general classes: (1) The sudden or abrupt withdrawal of morphine; (2) the gradual withdrawal of the drug; (3) the narcotic method.

The first or abrupt method of withdrawal is needlessly severe, causing the patient to suffer indescribable torture. This is the simplest and easiest method for the attending physician, as it consists merely in locking up the patient and leaving him to writhe in agony till the crisis is passed. This method is barbarous and unscientific and endangers the health if not the life of the patient. As it is wholly unnecessary to cause this suffering, it is remarkable that any institution should employ such drastic measures.

The gradual withdrawal method consists in so adjusting the doses of morphine that a slightly smaller amount is administered each day till zero is reached. This is a very satisfactory plan in cases that are not of too long standing and severity. Active medical treatment should accompany this method for the purpose of combating the withdrawal symptoms. These symptoms are always numerous and vary in different patients. By reducing the doses of morphine very slowly, and by the use of ameliorating remedies, these symptoms are greatly relieved.

The plan of treatment which I have denominated the narcotic method is, I believe, superior to all others in severe cases of morphinism. This consists in the use of various hypnotic remedies, so combined or alternated as to keep the patient asleep or in a quiet and comfortable condition for a short time, while the morphine is being completely withdrawn. When he awakes the period of suffering is passed, and all desire for morphine is gone. The painful part of the morphine withdrawal is accomplished while the patient is unconscious, on the same principle that a surgical operation is performed under the influence of anesthetics. The hypnotic remedy most often recommended for morphinism is hyoscine, administered in large and repeated doses. I consider this plan of treatment too uncertain to be recommended as a routine measure. While it may answer as an exclusive remedy in some cases, yet usually it produces delirium, and occasionally the delirium lasts for some time after the administration of hyoscine has been stopped. I have, however, often found it useful as an adjuvant to other sedative remedies, but many patients do not bear it well, and are made worse by its exhibition if it is not combined with other remedies. The exact remedy or combination of remedies must be determined by the idiosyncrasy of the patient, and occasionally several combinations will be tried before we find the one best suited to the peculiarities of the patient in hand. But, with experience, the physician will be able to get his patient promptly into the right condition for a total withdrawal of morphine, without pain and without danger.

A very important part of the treatment follows the withdrawal of morphine. Whatever method is employed, the patient is weak and debilitated for a time after the drug has been removed, and requires a course of tonic treatment and rest before he is fit to return to his usual vocation. If he leaves the sanatorium too soon he is very liable in his weakened condition to return to the use of morphine. Consequently the after-treatment is as important as any. This treatment consists in the use of remedies for the improvement of the appetite, the digestion, and the general condition of the nervous system. I often employ for this purpose high-frequency currents, mechanical vibration, and other therapeutic agents in addition to those of the pharmacopœia, and find them very valuable remedies and highly appreciated by the patients.

The victim of morphinism is usually a great sufferer and is deserving of as much sympathy and medical care as is given to any invalid. Because a patient has damaged his health by foolish habits is not a sufficient reason for professional neglect.

Many acquire the morphine addiction quite innocently, but even if the patient is entirely to blame for his condition we should remember that this is not the only disease for which the patients themselves may be responsible. In fact, a large proportion of the diseases that afflict humanity are caused directly or indirectly by foolish or unhygienic conduct. But this fact should not affect the physician's attitude, nor indeed that of the general public. In morphinism we have a serious pathological condition, and it is the business of the physician to devote his best energies to its cure. Every citizen should also be interested in it as a matter relating to the public health, that is of importance to the community. The self-administration of morphine is a great mistake, and its dangers should be more generally known. But we should not be too severe in condemning the errors of others. The only man who never makes a mistake is the one who never does anything. We are all composite creatures, made up of strength and weakness. To keep in mind this common heritage of the race, I have hung up conspicuously these lines:

"There is so much bad in the best of us,
And so much good in the worst of us,
That it hardly behooves any of us
To talk about the rest of us."

ON FLATULENCE AND ITS TREATMENT.*

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF INTERNAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

By the term flatulence a condition is designated in which an increased quantity of gas exists in the digestive tract. Two varieties may be differentiated, one in which the gas difficulty refers principally to the stomach—here eructations of gas or belching take place at frequent intervals—and the other in which the accumulation of gas exists principally in the intestinal tract—feeling of fulness in the abdomen and frequent passing of wind (flatus) per rectum.

Flatulence may exist as a primary disease or more frequently be associated with other ailments. Primary or idiopathic flatulence is a functional and nervous affection of the stomach or bowel, or both, in which the sphincter muscles of the digestive canal are principally concerned (relaxation of cardia or rectum).

There is no doubt that the quantity of gas emitted in this ailment is immensely increased over the normal. With regard to the origin of this ailment, the modern writers take quite a different view from that of the older clinicians. Formerly fermentation was believed to be at the bottom of the trouble. It was assumed that the carbohydrates and other food substances gave rise to undue fermentation and development of gas (fermentative dyspepsia). A disturbance of the act of digestion was assumed to exist, and the trouble, therefore, was considered a grave one. For the last twenty-five years, however, most clinicians have convinced themselves that flatulence may exist without any serious consequences for a long time. In most instances there is no real augmented fermentation of the food. The frequent eructation of gas or belching is explained on the theory that swallowing of air takes place at frequent intervals almost unconsciously (aerophagia, Bouveret). In this manner there need not always be an increased amount of gas in the stomach, but simply a swallowing of air and bringing it back again. My own experience is strongly in harmony with this modern view. I have frequently observed that in cases of ischochymia, in which there is almost always an undue fermentation and decomposition of food present (H_2S), patients do not suffer much from belching of gas. There may exist a feeling of tension in the stomach, but as a rule the cardia is perhaps rather more tightly closed than normally, due to the irritation by the decomposed substances. This is perhaps a provision of Nature not to let the patient become aware of the unpleasant odor which exists in his gastric cavity. On the other hand, frequent belching and expulsion of flatus exist in individuals who are well nourished and present no other symptoms whatever, indicating that the production of gas cannot be due to a grave lesion. Besides the swallowing of air a disturbed absorption of gas may exist. The latter incident is the principal factor in the augmentation of flatus.

A real increase in the formation of gas, and at the same time a diminution of its absorption, is encountered in acute and chronic gastric catarrh. A similar condition is met with in chronic enteritis, especially that variety in which the carbohydrate digestion is incomplete (fermentative intestinal dyspepsia of Schmidt). Here a feeling of fulness in the lower half of the abdomen and frequent passing of flatus are noticed by the patient. In these two classes of ailments the gas does not form the principal complaint of the patient, nor is it constantly present, in contradistinction from the above conditions in the so-called "flatulence." The main and almost only complaint of the patient is steady belching and flatus.

It is well known that gas under pressure is absorbed quicker than otherwise. Whenever the existing pressure is lessened by the frequent opening of the cardia and rectum, there is less liability of absorption. Habit in this way plays an important part in the origin and also in the aggravation of this trouble. The digestive canal can be trained to master the gases by quick absorption.

When our attention is actively kept up by some interesting or important subject also during sleep, the gases do not escape the digestive canal. It is merely in our easy-going hours, when our thoughts are turned to our vegetative function, that the need of passing gas makes itself felt. There is, however, no necessity of immediately responding to that sensation.

Secondary flatulence occurs in many affections of the digestive tract, in cardiac, circulatory, and respiratory disturbances. The feeling of constriction in the chest (want of more air and more space) is somewhat relieved by the propulsion of gas. The reason for this is the freer expansion of the lungs, which is made possible by the lessened tension within the abdomen. This, however, is only true when there is a real accumulation of gas present. The latter condition is met with occasionally in the above organic ailments, the patient finding relief after emitting the gas endeavors to repeat the same process whenever the feeling of oppression in the chest takes place. He then swallows air and brings it back again. In these instances the patient, after ridding himself of gas, may feel easier, but not really relieved.

In primary flatulence the main point is to instruct the patient that no harm is done if the gas is not emitted. He should, therefore, rather try to keep back the belching as well as passing of flatus whenever possible. With regard to diet, in simple eructation, there is no restriction whatever necessary; in flatulence due to disturbed absorption in the bowels it will be well to exclude from the diet beverages

*Read before the Brooklyn Medical Society, May 17, 1907.

charged with carbonic acid gas and most gas-forming foods (cabbage, beans, onions, and the like). Nerve sedatives may also be administered for a short while, and will be helpful in accomplishing a cure.

In secondary flatulence the primary trouble must be attended to. Aspiration of fluids, whenever such exist, will give relief by decreasing the tension; the administration of iodides, digitalis, etc., according to necessity. With regard to diet, in most of these instances it will be best to have the patient take small and frequent meals in order to avoid overfilling of the abdominal viscera.

REMOVAL OF A LARGE THYROID TUMOR OF THE NECK—APPARENT DEATH—RECOVERY UPON REMOVAL OF THE ARTERY FORCEPS.

By JAMES HUNTER WELLS, M.D.

PYENGYANG, KOREA.

IN CHARGE OF THE CAROLINE A. LADD HOSPITAL, PYENGYANG, KOREA; MEMBER OF THE MEDICAL MISSIONARY ASSOCIATION OF CHINA

As is well known, odd cases come in series of three! This coincidence recurs so often as to make one think that there is perversity among animate things as well as among inanimate. Although I do a good deal of general surgery in the little hospital I have charge of here, neck cases seem to be especially frequent. Scrofula being very prevalent, removal of enlarged glands is one of the common operations frequently called for. One of these came one day lately, and with the usual anesthetic, composed of eucaine 5 grains, adrenalin 1 dram, water 7 drams, injecting from 30 minims to even as much as 60 minims, we proceeded to take out the glands.

A few days later came in the case referred to in the title of this communication. The neck was enormously enlarged, breathing being difficult. The tumor, which was diagnosed as an enlarged thyroid, was somewhat movable and a little larger than one's double fists, and it looked as if removal would not be difficult. The difficulty in breathing made the local anesthetic not only preferable, but the only kind which could be advised, though it was expected that some pain would necessarily follow. The work proceeded properly, though it seemed at one time as if it would be impossible to get the tumor out without involving the trachea, it was so firmly imbedded and so very adherent. By carefully using fingers only it was removed from the trachea, and so out. Bleeding was free, of course, but mostly venous. The large cavity filled up rapidly with blood, and I grasped several places with forceps. Suddenly the woman gasped, struggled, and stopped breathing. Artificial respiration did no good, and, with staring eyes, blue lips, and every appearance of death, she quivered and then was quiet. The three doctors (two happened in as visitors) pronounced the woman dead—so did I. The husband, standing near, was told she was dead, and went out crying. I then concluded to remove the artery forceps, bleeding having completely stopped, and fix the body up to remove. There were perhaps a dozen artery forceps altogether. On removal of the forceps you may imagine our surprise and delight to note that the woman was coming to and quietly resuming breathing! The respiration rapidly became normal, the patient went on to complete recovery, and the operation was a success. When her husband was called back and informed that his wife was living, he would not come and did not believe it. He was finally persuaded, but I think he was somewhat chagrined to be covered from the shock and strangeness of it all.

Now, what was the cause of the trouble? I supposed, and am inclined to think yet, that it was due to grasping the pneumogastric nerve, though I thought it was quite far enough out of the way. The condition was not due to the local anesthetic; of this I am sure, for I have operated hundreds of times in which I used much more, and with the same solution, and had no bad effects.

I am not satisfied with the pneumogastric explanation, and so report the case, hoping I may get a more satisfactory explanation than any offered. Would just the removal of such a large tumor, with its intimate nerve supply, produce sudden symptoms of paralysis as here reported?

Two days afterward a smaller but deeper cyst—about the size of an egg—presented, and I removed it without any trouble, for having "waded in" on the other made me feel confident that almost any kind was removable if one can take time and use the local anesthetic. This makes the three, but finally, to explode the idea of "a series of three," a few days later another came, which was so large and adherent that I was obliged to pronounce it inoperable.

CANCER OF THE HEAD OF THE PANCREAS.

By DELL B. ALLEN, Ph.B., M.D.,

NEW YORK.

ASSISTANT PHYSICIAN TO THE PRESBYTERIAN HOSPITAL DISPENSARY; INSTRUCTOR IN MEDICINE, FORDHAM MEDICAL COLLEGE.

PATIENT, male, colored, 45, family history negative. Enjoyed good health until five years ago, when he had an attack of appendicitis, for which he was treated medicinally. Since then he has been habitually constipated and had occasional attacks of acute pain. For the last eighteen months he has complained of a constant dull, aching pain in the epigastrium, worse when the stomach was empty, but three or four mouthfuls satisfies appetite and relieved the pain for a time. He suffered from constant nausea, occasional vomiting, anorexia, coated tongue, constipation, and jaundice. The attacks of acute pain and vomiting have been recurring with increasing frequency during the last six months. There has been marked loss of flesh.

He had on admission intense acute pain over the entire abdomen, more pronounced in the epigastrium, and was vomiting large quantities of water. No movement of bowels; cold, clammy skin, temperature subnormal, heart weak and irregular. The stomach was dilated almost to the symphysis and over to the right side. A stomach-tube was passed, and a large quantity of gas forcibly expelled, followed by about a quart of water. The pain was relieved and stomach reduced in size. There was a mitral murmur.

The temperature subsequently rose to 99.2°, but fell the next day to normal and remained there. The pain assumed a dull, constant character, increased by swallowing and on motion; no vomiting, no defecation. On the third day he had an attack of hiccoughs which lasted about eighteen hours, and was stopped only by cocaine. On the fourth day he began vomiting a brownish fluid with slight fecal odor. A palpable lump now appeared along the ascending colon. Diagnosis made of intestinal obstruction or intussusception, and immediate operation advised. At the operation, on opening the peritoneum, a quantity of gas escaped. The lumen of the small intestine was narrowed at intervals by bands of adhesions. There was a thickened mass in the head of the pancreas which proved to be carcinoma. There was no fat necrosis. The gall-bladder, liver, stomach, and large intestine were normal.

New York, September 14, 1907.

THE EFFECT OF THE ROENTGEN RAYS ON THE KIDNEYS.

BEFORE proof to the contrary had been adduced it was generally believed that the *x*-rays had an effect only on the superficial portions of the body which were exposed to their action. Within a few years it has been shown that the lymphoid tissue over the entire body is affected by this agent and that the testicular functions are likewise disturbed. Its action on the other internal organs, however, constitutes a practically unexplored field for study, as the observations which have thus far been made are too incomplete to warrant any definite conclusions. As regards renal changes we are very much in the dark, for the few observations which have been published seem to indicate that the kidney epithelium is quite resistant to the action of the *x*-rays, and that no renal changes are produced by this agent. The paucity of our knowledge on the subject lends interest to the valuable paper published by A. S. Warthin in the *American Journal of the Medical Sciences* for May, 1907, which is based on the kidney changes discovered in the material from two cases of leukemia that had been treated for some time with the *x*-rays. In one the leukemia was of the myeloid type, the white cells numbering 800,000 and the spleen being greatly enlarged. Under the use of the *x*-rays the patient's condition greatly improved and after seven months of treatment it was believed that a cure had been attained. Six months later the symptoms returned and necessitated renewed treatment, but death finally ensued with evidences of a severe intoxication. The autopsy showed that the leukemic condition had evidently been transformed into an aleukemic one. The kidneys, however, showed a most remarkable change, the greater part of the renal structure being replaced by calcareous deposits, producing a picture similar to that which is seen after poisoning with mercuric chloride. The renal epithelium seemed completely necrosed. In another case of leukemia a similar deposit of lime salts was found in the kidneys, the patient having died, after a period of apparent improvement, with evidences of intoxication like those observed in the first patient.

The presence of this extensive calcification naturally arouses interest as to the posible connection between this condition and the treatment employed. Warthin examined the kidneys in twenty-five cases of leukemia which had not been treated by the *x*-rays and in no instance were any evidences of calcareous degeneration found. In all there was more or less extensive parenchymatous degeneration in the kidneys and its extent seemed in direct proportion to the number of degenerating white cells seen in the blood and other organs. Warthin believes that the more severe renal changes seen in the two cases of irradiated leukemia are the results of some poison arising from the excessive destruction of white cells by the *x*-rays. In order to substantiate this theory the writer undertook a series of animal experiments, a considerable number of the smaller animals being employed for the purpose. It was found that degeneration of the renal epithelium occurred in all cases, its extent depending on the length of time the animal had been exposed to the *x*-rays. Continuous exposure was apparently always fatal, the rapidity of this result invariably depending on the amount of lymphoid destruction and the extent of the kidney lesion. The character of the symptoms, however, suggests a primary or secondary damage to the central nervous system, probably from an intoxication similar to that which results from the products of protein destruction.

A practical application of these observations would seem to warrant the assumption that the great destruction of leucocytes as it occurs in the *x*-ray treatment of leukemia may be extremely dangerous. From an occasional radiation of the body it is hardly likely that any serious damage to the kidneys will result, but when the process is repeated and prolonged, as in leukemia, the possibility of renal injury must be borne in mind. The condition of the kidneys should therefore be carefully watched by frequent examination of the urine, for, especially when a previous nephritis is present, an exacerbation may readily occur. The article here referred to constitutes a valuable contribution to our knowledge of a therapeutic measure which is undoubtedly of service, but regarding whose characteristics we are not yet sufficiently or satisfactorily informed.

THE EFFECT OF FEVER UPON THE RESISTANCE OF THE ORGANISM TO INFECTION.

IN the development of scientific medicine the significance of fever accompanying acute infections has always claimed the attention of the clinical observer. Long ago there arose the theory that fever is a conservative phenomenon, and accordingly those cases that ran their course without high temperature and the other elements of this symptom-complex, came to be regarded as especially severe and dangerous forms of the disease in question. The first blow to this view was delivered by Liebermeister ("Handbuch der Pathologie und Therapie des Fiebers"), whose studies uncovered many of the deleterious effects of fever upon the tissues and the organs of the body. Later, however, the observations of the effect of heat upon the life-processes of microorganisms, which soon came to be regarded as the true causative agents of many diseases, led to a revival of the ancient conception of fever. High temperature *in vitro* certainly inhibits the growth and the activity of many bacteria: it was argued, accordingly, that similar temperatures *in vivo* produce the same effect. Soon, however, the objection was brought forth that our knowledge of the localization

of high temperature in the body is not sufficient to allow the conclusion that the various bacterial excitants of disease are subjected to the same degree of heat that is registered by our thermometers (Krehl). Moreover, it became a question whether the inhibitive effects of fever upon the cellular excitants of disease were not made up for by a like inhibitive effect upon the body cells of the patient.

Lately, the attention of laboratory workers has been attracted to the subject, and the attempt has been made to reproduce the clinical condition, in part at least, by animal experiments, and thus to study the effects of the phenomenon at first hand. In *Russkii Vratch*, No. 25, 1907, Dr. V. P. Barankieva gives the results of her recent studies in this direction. She believes that a most important question in this connection is the behavior of the organism in fever toward the microbes that are probably constantly gaining entrance to the fluid channels of the body and are then rendered harmless by the bactericidal properties of the cells and of their products. She produced high temperatures in rabbits by means of the so-called "thermal puncture" of the brain (Aronsohn, "Allgemeine Fieberlehre," 1906), killing the animals in the height of this condition. Bacteriological examinations of the organs showed in such cases the constant presence of *Staphylococcus albus* and of a streptococcus. She concludes, accordingly, that fever may lead to an infection of the organism by the bacteria that are constantly present on the surface, and ever ready to effect an entrance when opportunity offers. Fever, therefore, seems to diminish the resistance of the cells of the organism.

Still more interesting experiments were made with the aim of studying the effect of fever upon natural immunity of animals. Rabbits were inoculated with the pneumobacillus of Friedländer, to which they are normally very resistant. The natural immunity of the animals was shown to be much diminished or completely lost in the presence of fever experimentally produced, the animals dying of lesions in the lungs accompanied by many focal necroses in the liver and spleen. Then a laboratory culture of staphylococcus of well-known virulence for rabbits was used, and again the effects of high temperatures proved to be the same; the infections were more virulent and their course more rapid than was usually the case.

These experiments throw a flood of light upon the etiology of mixed infections, and perhaps upon the increased susceptibility of individuals affected by acute diseases of brief duration with high temperatures, such as influenza or tonsillitis, to other more serious infections—pneumonia and tuberculosis for instance. Of course, all the data given above require further development and corroboration, but they certainly point the way to interesting experimental possibilities, the study, for instance, of the action of antipyretics in the course of experimentally produced fevers, and so on. Meanwhile, however, it is perhaps wise to hold in check the present tendency to consider all phenomena observed in the organism in the course of an infection in the light of the wonderful conservative process, and the custom of was finally persuasive noninterference in such cases. covered from the shock enough that the various organs

Now, what was their constituent cells meet the injurious forces assailing them by a striking variety of defensive processes and activities, but such reactions, once started, may not be inhibited at the proper time; it may be the part of wisdom, therefore, in such cases as the high temperatures discussed above, to interfere at some point with the local or general manifestations of the conservative process, in the interests of the organism as a whole.

CANCER HOUSES.

The old question of "cancer houses," one of the arguments employed by the adherents of the parasitic theory, has been revived in Paris by the publication of a report to the Prefect of the Seine of the Sanitary Bureau of that city. A commission appointed to study certain facts in regard to the localization of tuberculosis added to its labors an investigation of that of cancer. From August 1 to December 31, 1906, 1,062 deaths from cancer were reported to the Board of Health of Paris. Grouping these deaths by houses, Mr. Paul Juillerat, in his report, found that in 1,008 houses there was but one death each; in two houses there had been two deaths each during the year; in one convent there had been four deaths, and in five asylums and homes for the aged there had been in all twenty-six cases. These cases are, of course, not conclusive, or even significant in themselves, but it is the intention of the Health Department to continue the observation for a number of years in order to see whether there are any houses among the dwellers in which cancer is especially prevalent. The statistics would be more valuable if it could be noted in what houses the disease first declared itself, as well as those in which its victims finally succumbed.

Dr. Alfred Fillassier, writing in the *Gazette Médicale de Paris* of August 15, has collected a number of cases of these so-called cancer houses. In one apartment in a house at Vouziers, the husband, wife, father-in-law, and a servant died of cancer between 1870 and 1875. In another house at Oyonnax three successive tenants, unknown and unrelated to each other, died within a period of four years. In another case five persons, belonging to three different families, died in a farm house in the course of forty years. In another house at Jassy, eight families lived at various times in the course of twenty-five years; in each of these families a case of cancer occurred, and in one there were two cases. The writer of this paper promises further statistics regarding the domiciliary prevalence of cancer when he has completed a study of the family histories of the cases admitted during a series of years to a home for inoperable cancer sufferers. The undoubted instances of cancer cages observed during the study of Jensen mouse tumor have directed attention anew to this subject, and the study of fresh instances of house endemics of cancer promises to bring out facts of interest and possibly of significance in the etiology of malignant growths.

Subcutaneous Injuries of the Abdomen.

A blow on the abdomen or a severe concussion of the body resulting from a fall from a great height upon the pelvis, feet, etc., may injure the abdominal organs, while the elastic abdominal wall entirely

escapes injury. This is mainly true of the solid organs, any of which may suffer a rupture of varying degree, especially if they are diseased. The intestines usually escape, while the liver is most likely to be injured. These injuries prove fatal by internal hemorrhage or by a general peritonitis. As both of these conditions can be treated, the prognosis depends upon an early diagnosis. The difficulties and importance of an early diagnosis have been again emphasized by Dr. T. Vöckler in the *Münchener medizinische Wochenschrift* for August 13, 1907, where he discusses them in connection with a case of rupture of the liver. The signs are often very indefinite at first, so that the decision whether any, and, if so, what organ is injured, is difficult or impossible. It is not so important to diagnose which organ is involved as it is to know whether an internal injury really exists, for the treatment is laparotomy, no matter which organ is injured. The symptoms of any internal injury consist in more or less marked manifestations of shock, i.e. pallor and coldness of the skin and visible mucous membranes, dilated, slowly-reacting pupils, irregular, weak pulse, at times nausea and vomiting, and frequent fainting spells. But this symptom complex is also seen as a result of internal hemorrhage, and, after simple contusions of the abdominal wall without intraabdominal injuries, and it is difficult to determine whether it is just due to a simple contusion of the abdominal wall, or whether the symptom complex is a manifestation of an internal hemorrhage. It is due to the latter if the symptoms do not decrease, but increase, as time goes on and continue longer than two hours; thus the pulse will become more rapid and the pallor more marked. If nothing else speaks for an internal injury, these symptoms alone suffice to make a diagnosis. Other symptoms, such as general abdominal tenderness, may also be of value. Rigidity of the abdominal wall, most marked over the injury and increased by touching the abdomen, when present, is a sign of internal hemorrhage; to ascertain its presence early the patient must be told to breathe with his mouth open, and not too deeply. This rigidity must be constant, for, when transient, it may be due to a simple contusion of the abdominal wall. Vomiting is a late sign unless stomach or intestine is the seat of the injury, in which case the other symptoms of a general peritonitis usually set in as early as six hours after the injury. If an internal hemorrhage is present, signs of fluid in the abdominal cavity can be made out in one-half to two hours after the injury. Its location aids to a certain degree in diagnosing which organ is injured; if it is caused by rupture of the spleen, it is usually confined to the upper left portion of the abdomen; if it is due to a rupture of the liver, it is general or confined to the right side. As regards the treatment, shock is abated by the dorsal position and heat. As the first period of shock is often followed by a period of ease, the patient should be closely watched and sent to a hospital at once, so that an operation can be performed immediately if the occasion demands it. To be on the safe side, nothing should be given by mouth or rectum, as this only favors a general peritonitis in case the stomach or intestine is injured. Too much stimulation is bad before the source of hemorrhage is stopped; morphine should be withheld, lest it mask the symptoms. The patient should be catheterized immediately after the injury, for, if no urine and only blood is obtained, we know the bladder is injured; while if bloody urine is obtained, it points to a kidney lesion. If the rupture in the liver or spleen can be easily reached, and has clean-cut edges, it may be sewed; otherwise it is best to pack it. If the pancreas is injured the abdominal wound should always be drained, as its secretion injures tissue and causes fat necrosis. A pancreatic fistula is best treated by putting the patient on an antidiabetic diet, as carbohydrates increase the flow, while a fatty diet diminishes it.

Typhoid Bacilli Carriers in Institutions for Chronic Invalids.

It has long been known that typhoid bacilli are excreted with the feces and urine of patients suffering from typhoid fever. It has also been discovered more recently that bacilli may be excreted for years after the patient has recovered from the disease, not necessarily with each stool, but at intervals. Dr. A. Nieter reports in the *Münchener medizinische Wochenschrift* of August 13, 1907, an attempt to trace the etiology of several typhoid epidemics in a large insane asylum. After excluding such sources as water and foodstuffs, he made examinations of the stools of all the inmates, and found seven patients with typhoid bacilli in the stools. All of these were well and up and about. After isolating these seven cases, he thought no further epidemics would develop, but only a few months later three new cases developed in the same building from which the seven had been removed. Water and foodstuffs were again excluded as sources of infection, and the stools of all the patients were again examined for typhoid bacilli. One patient was found excreting the bacilli. She had been in the institution several years, and examination of her stools during the previous epidemic showed negative results, proving that the excretion of bacilli is not constant. She felt well and had a positive Widal of 1:6,000. Similar findings in this and other institutions were reported, and in some no further epidemics developed after isolating the carriers. It is therefore important in all large institutions for chronic invalids, where the patients remain for a long time, to trace the etiology of each case of typhoid fever. When by repeated examinations of the stools of all the patients, carriers of typhoid bacilli are detected, they should be isolated.

News of the Week.

The Sixth International Dermatological Congress has been in session at the Academy of Medicine, New York City, during the present week. At the meeting on Wednesday, Prof. Thomas De Amicis, of Naples, Italy, was elected President of the next Congress, which is to be held in Rome in 1910.

Cholera.—It is reported from Russia that cholera is spreading in St. Petersburg and householders in that city have been warned by the health authorities to observe the strictest precautions in the preparation of food, in the use of boiled water, and in disposal of refuse. The disease is also epidemic at Nijni-Novgoro'l, where from ten to fifteen new cases are reported daily. A Russian emigrant died recently of cholera on a train while passing through Prussian Poland. This was the first case discovered this year in German territory, but a day or two later a raftman on the Vistula died of the same disease after reaching Prussian territory.

The Plague.—Up to September 7 there had been eighteen cases of bubonic plague in San Francisco. The first case of plague occurred at the U. S. Marine Hospital on May 27, and the next case was not discovered until August 12, when two cases appeared at North Beach. The burned district is said to be alive with rats, and every effort is being made to exterminate them.

recommended to the Board of Supervisors that the City and County Hospital, which has sheltered a number of plague cases, be burned. The hospital is a collection of frame buildings, which the city authorities have long planned to destroy. The announcement is made that the Marine Hospital Service is to take charge of the plague situation. Dr. Rupert Blue has been assigned by Surgeon-General Wyman to direct the campaign.

Smallpox in Vienna.—Smallpox is prevailing to such an extent in Vienna that it has been declared epidemic, and public meetings and processions have been forbidden. Within a week more than 160,000 persons were vaccinated.

Koch's Work in Central Africa.—It is reported that Prof. Robert Koch has been meeting with unvarying success in his treatment of sleeping sickness by atoxyl, having had about four hundred cases of the disease. His fame has spread throughout Central Africa, where he is known as "the great white wizard," and appeals to him for help are constantly coming from the most remote regions where the disease prevails.

Civil Service Examination for Anatomist in the Army Medical Museum, Washington.—The United States Civil Service Commission announces an examination on October 23-24, 1907, at the usual places, to secure eligibles from which to make certification to fill a vacancy in the position of anatomist (male), at $1,600 per annum, in the Army Medical Museum, office of the Surgeon-General, and other similar vacancies as they may occur there. The examination will consist of the following subjects: (1) Human anatomy, (2) anatomical drawing (competitors will be required to make a pen-and-ink drawing from a photolithograph which will be furnished), (3) gross pathology (of tissues), (4) construction, care, and use of microscope (questions relating to the compound microscope, with knowledge of various makes in general use), (5) training and experience (rated on application). Two days will be required for this examination. The first subject will be given on the first day, and the remaining subjects on the second day. Age limit, 20 years or over. It is desired that the person appointed to this position should be young, in good health, have a thorough knowledge of anatomy (preferably, but not necessarily, a graduate in medicine), be able to make anatomical drawings, understand microscopes, surgical instruments and appliances, and be able to prepare, card, and keep in order the anatomical specimens of the museum. This examination is open to all citizens of the United States who comply with the requirements. Applicants should at once apply to the United States Civil Service Commission, Washington, D. C., for application Form 1,312.

Chicago Dispensaries.—In Chicago, where dispensary records are not yet kept with the exactitude desired by the committee of the Chicago Medical Society now working in that direction, twenty-nine of the fifty-five dispensaries duly listed last year, treated 223,110 persons, the sixteen dispensaries in which figures are carefully balanced reporting the visits of 93,800 persons, with a total of 236,140 treatments. The number of applicants refused attention, because palpably able to pay outside physicians, was 1,170. Since the investigation of dispensary applicants, though now partially conducted by the Chicago Bureau of Charities, has not yet become general or thoroughly systematic, these figures must be taken as mere suggestions of the true state of affairs. In order to correct the abuse of medical charity a committee was appointed, consisting of Drs. C. W. Green, E. A. Fischkin, W. Van Hook, J. B. De Lee, J. M. Dobson, D. A. K. Steele, and T. B. Renn, chairman. This committee has just made the following recommendations: (1) That a committee be appointed by the president of the Chicago Medical Society, whose duty it shall be to bring into one federation the managers of all reputable dispensaries for the purpose of overcoming the evils that now exist through cooperation of the dispensaries themselves, by the education of the public and of those who apply for treatment, through the public press, if need be, and, if this is not successful, to inaugurate legislation to correct this abuse. (2) That all dispensaries be required to keep complete records of all cases, which records should be open to the inspection of the officers of the federation, and that all dispensaries be required to furnish sanitary and hygienic accommodations for both sexes, which should be inspected by the Department of Health. We also recommend that these facts be brought to the attention of the Commissioner of Health. (3) That all dispensaries should have a sign in a conspicuous place, stating that the free dispensary is for the deserving poor only, and should employ a distributor, who should inquire carefully into the ability of the patient to pay, referring all doubtful cases at once to the Chicago Bureau of Charities for investigation. (4) That none but the deserving poor should receive treatment or should be received at any dispensary, and these should be required to sign a statement that they are not able to pay. (5) Wherever possible, all patients treated gratuitously at free dispensaries should be used for teaching purposes, as this tends to systematize the record of cases, and gives the patient more careful and helpful treatment.

A Trolley Hospital.—A hospital car was recently placed in service on the street railway lines in Milwaukee. The interior of the car is fitted with three leather upholstered permanent stretchers. Hooks are placed in the side near the ceiling, from which a fourth stretcher may be suspended. At either end of the car are stationary cabinets supplied with complete surgical outfits, consisting of all necessary instruments, as well as dressings that might be called for in emergency cases. The car is electrically heated, and water in a two-gallon tank fed from a larger receptacle may be heated in the same manner. The car is not designed for city work, but in outlying districts, far removed from a hospital, first aid will be direct on the ground instead of bringing the sufferer to the city. The car was built and equipped after plans prepared by Dr. C. H. Lemon of Milwaukee.

A Launch for Dr. Grenfell.—A large gasoline launch was recently sent to Labrador from Gloucester, Mass., for use by Dr. Grenfell, the medical chief of the mission to the Labrador fishermen. The launch will be used for making trips along the coast to fishing stations that cannot be reached by the regular steamer of the mission.

Garbage Barrels for Food.—Orders have been issued by Health Commissioner Darlington to contractors handling the garbage and refuse of the city, that the practice of selling to produce and meat dealers for further use the empty barrels and boxes in which waste matter has been carried to the dumps must be discontinued. The order follows an investigation which was made in response to the complaint of a citizen.

New Laws.—On September 1 two new laws affecting pharmacists became effective. One of these forbids substitution in the compounding of prescriptions, and the other makes it a felony to sell cocaine or any compound containing it, except upon

the written prescription of a duly registered physician.

Powerful Drugs.—The *British Medical Journal*, in making an investigation of some of the British public's favorite quack remedies, gave the result of an analysis of a bottle of 200 pills largely sold in England. The most careful tests failed to reveal the presence of any drug, the pills being pure sugar without any admixture whatever. The bottle of two hundred pills, which were made in America, sold at retail for a shilling.

Another Cancer Cure.—A despatch to *The Sun* from Budapest states that Dr. Haler of that city has secured very beneficial results in cancer cases at the University Hospital through the use of an injection of gelatin. In forty cases thus treated he claims to have been successful in all but three.

The Pollution of Lake George.—The Attorney-General of the State has announced, in answer to a complaint from the New York State Board of Health regarding the pollution of the waters of Lake George by the steamers plying thereon, that he has no authority to prosecute the company owning the boats. Under the navigation law the penalties for such violations go to the adjacent towns, and it is only the officers of those towns who are empowered to prosecute.

Private Cups at Public Fountains.—The W. C. T. U. has offered to present a drinking fountain to the town of Bloomfield, N. J., and the town council has accepted the offer. The Board of Health, however, announces that it will not allow cups for public use to be placed on the fountain because of the great danger of the spread of disease through the use of such utensils.

Payment for Birth Certificates.—Hereafter every baby born in Michigan will cost the county into which it has come 75 cents. A law passed by the legislature last spring provides that all physicians, midwives, or nurses who file their birth certificates, properly made out in black ink, with the registrar within ten days after the birth, will receive a compensation of fifty cents for each certificate. In addition to the compensation for the physicians or others making out the certificates, the registrars receive 25 cents for their services in recording and forwarding the same to the department at Lansing.

Fraternal City Sanatorium.—The first buildings of this sanatorium, intended for the tuberculous members of various fraternal organizations, are now completed and patients are being received. The sanatorium is located on a plateau in New Mexico, about four miles from Alamogordo, at an elevation of 4,750 feet above sea level, not far from the Marine Hospital Sanatorium at Fort Stanton and the Army Sanatorium at Fort Bayard. The buildings now completed include the large general building and immediately east is located the service building. The former is a structure nearly 300 feet in length, having a second story for about half its length. The sleeping rooms are arranged in groups of two, each group being separated by covered porches, and between the rooms are located the toilets, one for each suite of two rooms. Accommodation is now ready for 250 patients, and it is intended to add to the capacity of the sanatorium indefinitely.

Woman's Medical College Hospital in Philadelphia.—Plans have been prepared for a new hospital building for the Woman's Medical College of Pennsylvania. The proposed new structure will be six stories in height, of brick and concrete, and it will adjoin the college building. It will have a front of 74 feet and a depth of 87 feet. The first floor will be divided into offices, receiving room and students' rooms, with a large operating amphitheater, two stories high, with a glass roof. The second story will be given up to private rooms. On the third floor will be two public wards and two private rooms. Fourth, fifth, and sixth floors will be given over to private patients, nurses, and attendants. A roof garden for convalescents will surmount the entire structure.

The Chicago Eye, Ear, Nose, and Throat College has purchased property adjoining the present site of the College, and it is proposed in the near future to build a new building occupying both the old and new sites. The building will be an eight-story fireproof structure, with a forced draft ventilating system. During the erection of the new building there will be no interruption of the business of the institution, as one-half will be erected and occupied while the other half is being gotten ready.

Tuberculosis Hospital in Milwaukee.—Work will be begun soon on the tuberculosis annex to the Milwaukee County (Wis.) Hospital at Wauwatosa. The structure will be of brick, two stories high, and will provide accommodation for forty patients, fifteen women and twenty-five men.

The Hudson Street Hospital.—An annex is to be built for the Hudson Street Hospital to provide accommodation for the increasing number of emergency cases. The annex, located in the rear of the hospital, and connected with it by a covered bridge, will be 55 by 26 feet and three stories high.

Tuberculosis Hospital at a Prison.—The Tennessee Prison Commission has decided to erect a tuberculosis hospital at the Brushy Mountain mines. The State Board of Health is cooperating with the Commission, and the hospital will embrace the idea of both the bodies.

A New Medical College.—The College of Physicians and Surgeons of Meridian, Miss., has purchased ground upon which it will at once erect a college building and hospital.

Scarcity of Milk in New York.—It is said that the city is threatened with a partial milk famine, there being at present a shortage of 80,000 quarts, which may be expected to be even greater when all the families now in the country have returned to the city.

International Milk Congress.—The second international congress of the Gouttes de Lait Association was held this week in Brussels. Among those present were Mr. Nathan Strauss and Dr. Arthur Randolph Green, director of the Strauss laboratories for the pasteurization of milk.

The San Francisco Board of Health.—Mayor Taylor has appointed a new Board of Health, composed of Drs. Thomas W. Huntington, Dudley Tait, and William Ophuls, in place of the old Board appointed by former Mayor Schmitz.

Dr. Arthur A. O'Neil has been appointed by Mayor Taylor warden of the San Francisco City and County Hospital, to succeed an appointee of the deposed Mayor Schmitz.

A New Association of Physicians was organized at the Sherman House (Chicago) recently, with Dr. Charles McCormick as president and Dr. C. W. Crosby as secretary. Directors will be selected at the next meeting of the organization. The objects of the association are announced to be to secure insurance against malicious prosecution; to

secure speedy changes in the laws of the several States so as to permit a licentiate to practice medicine in any State of the Union; to have members of health boards appointed from all walks of life, and to publish a medical magazine.

The Wisconsin State Medical Society held its annual meeting at Superior on August 21-24. The officers elected were: *President*, W. E. Ground, Superior; *First Vice-President*, Byron M. Caples, Waukesha; *Second Vice-President*, Dr. Herman Gasser, Platteville; *Third Vice-President*, Dr. E. S. Hayes, Eau Claire. Milwaukee was chosen for the next meeting place.

The Piscataquis (Me.) Medical Association.—At the annual meeting of this society held two weeks ago, the following officers were elected for the ensuing year: *President*, Dr. H. A. Snow, Milo; *Vice-President*, Dr. A. H. Stanhope, Dover; *Secretary*, Dr. C. W. Ray, Sangerville; *Treasurer*, Dr. E. A. Thompson. A banquet at the Blethen House followed.

Fifth District Medical Society of Arkansas.—At the annual meeting of this society, held at Dardanelle in the last week of August, the following officers were elected: *President*, Dr. Norborn H. Jackson of Pontoon; *Vice-President*, Dr. J. S. Kalb of Clarksville; *Secretary and Treasurer*, Dr. S. P. Vaughter of Little Rock.

Obituary Notes.—Dr. Richard Botsford of Lake City, Iowa, died on August 30 at Fort Dodge, following an operation for gallstones. He was born in Fort Dodge in 1874, was graduated from the Medical Department of the University of Vermont in 1898, and practised for a few years in Burlington. Later he removed to Lake City, Iowa.

Dr. Joseph A. Winkler of Boston died on August 20, at the age of seventy-seven years. He was born in Savannah, Ga., and was graduated from the New York University Medical College in 1854. He practised in Savannah until 1865, when he went to Jamaica Plain, Mass., where he had lived ever since.

Dr. Daniel H. Kelley of Old Town, Me., died August 28, at the age of fifty-two years. He was born in Milford, Me., and was graduated from the Medical Department of the University of Vermont in 1881.

Dr. Henry J. O'Donnell of Ellsworth, Kan., died August 23. He was born in Ireland in 1866 and came to the United States in 1884. He was educated at Queen's College, Galway, and obtained his medical degree from the Bellevue Hospital Medical School in 1891. He was surgeon to the Kansas National Guard in 1895-6, and in 1905-6 represented Ellsworth county in the State Legislature.

Dr. Charles F. Branch of Amherst, Mass., died August 27, of Bright's disease, at the age of sixty-one years. He was born in December, 1845, in Orwell, Vt. He was a graduate of the Medical Department of the University of Vermont in 1879. He practised first in Coventry and later in Newport, Vt. He was professor of hygiene in the University of Vermont, Surgeon-General of the Vermont National Guard, and president of the Vermont State Medical Society in 1895. He removed to Amherst in 1896.

Dr. C. A. Kiemmer, formerly of Minot, N. D., and later of Faribault, Minn., died recently in Berlin, where he went last May to study in special courses. He was a graduate of the University of Minnesota College of Medicine and Surgery at Minneapolis, in the class of 1904.

Dr James Harris died in Yokohama on August 1, at the age of 81 years. He was born in Providence, R. I., and was graduated from the New York University Medical College. He entered the Russian army as Surgeon-Major during the Crimean war. His services there were appreciated and he received the Crimean and St. Petersburg medals. Returning to the United States, he entered the Federal army at the outbreak of the Civil War as Surgeon of the Fifth Rhode Island Regiment. In 1867 he was sent to Japan with the warship *Stonewall*, and never came back to America, but settled in Yokohama, where he practised medicine for twenty-three years. He retired from practice in 1890.

Dr. Charles L. Frankel of Berlin died August 27, at the age of forty-one years. He was a graduate of the St. Louis College of Physicians and Surgeons in 1892.

Dr. Lewis Mayo of Sauk Rapids, Minn., died August 25, at the age of seventy-nine years. He was prominent in political life as well as in medical practice, having been coroner, treasurer, and probate judge of Benton county and State Senator in 1870.

Dr. William Gutch of Albia, Ia., died August 24, at the age of eighty-three years. He was born in England, but came to this country in early life. He was a graduate of the Western Reserve Medical College, Cleveland, in 1855.

Dr. Edward J. Messemer of this city died two weeks ago at Marburg, Germany. He was born in New York and was graduated from the New York University Medical College in 1871. He was a member of the State and County Medical, Neurological, and the German Medical Societies, and was for thirty years an attending physician to Mt. Sinai Hospital Dispensary.

Dr. Joseph A. Krieger died recently in St. Louis. He was a graduate of the Missouri Medical College in 1888.

Dr. Nathaniel W. Webber of Detroit died August 30, at the age of 66 years. He was born at Gardner, Me., but removed when a child, with his parents, to Chicago. He was studying medicine at the time the Civil War began, and entered the army as hospital steward; later he was appointed assistant surgeon, and, on the retirement for ill health of his chief, surgeon. At the close of the war he completed his medical course, and was graduated from the Northwestern University Medical School, Chicago, in 1866. In 1869 he removed to Detroit, where he became professor of anatomy in the Detroit College of Medicine.

Dr. William H. Abercrombie died in Washington, September 5, at the age of sixty-five years. He was born in New York, and was graduated from the Homeopathic Medical College in this city in 1872. He practised medicine here and in Jersey City until 1890, when he was appointed Consul at Nagasaki, Japan.

Dr. William A. Rocap died at Olney, Philadelphia, on August 20, at the age of thirty-eight years. He was graduated from Jefferson Medical College in the class of 1888, and was for two years resident physician in the Jewish Hospital.

Dr. Bernard Zweighaft of this city died suddenly at Kennebunk Beach, Maine, on September 1, at the age of forty-one years. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1891.

Dr. Michael Beshoar died in Trinidad, Col., September 5, at the age of seventy-four. He was born in Pennsylvania, graduated from Ann Arbor University in 1853, and was the last survivor of his class. He was a surgeon in the Confederate Army.

Correspondence.

DENTISTRY WITH THE ETRUSCANS 2,300 YEARS AGO.

To the Editor of the Medical Record:

Sir:—One of the recent numbers of the journal, *Rivista Italiana di Odontoiatrica*, contains an article by Prof. Galli on the practice of dentistry in the land of the Etruscans in the fourth century before Christ. Upon carefully examining a skull dug up in the necropolis of an Etruscan city, he found old dental work consisting of four golden capsules or crowns, two of which covered natural teeth and had the other two as a bridge between them. Galli is convinced that his discovery shows the work of ancient Etruscan dentists; they also filled decaying teeth very well, and their crown and bridge work has stood the test of ages. In concluding he says that through American skill and invention dentistry has made wonderful progress, indeed, but it would seem that the foundation of the art had been laid away back in the early Roman times.

Leonard Weber, M.D.

APOMORPHINE IN ACUTE ALCOHOLISM.

To the Editor of the Medical Record:

Sir: In the issue of July 27, in an article, "Apomorphine in Acute Alcoholism," I note the statement that this hypnotic use of the drug was first given the profession by Douglas in 1899. This struck me as singular, since at that date I myself, then only a medical student, knew of the method, among my father's case records, of an alcoholic whom we have observed for twenty-five years. I find its use as far back as 1891. As at no time did my father (since dead) speak of the method as original, but rather taught it me as a recognized method, I believe the method must have been fairly generally known eight or nine years prior to 1899. J. E. Tuckerman, M.D.

EYE BORING OF SIGHTLESS CHILDREN.

To the Editor of the Medical Record:

Sir:—I shall be much obliged if you or some of your readers can give me an explanation of why blind babies and little children so constantly dig their fingers into their sightless eyes. I am deeply interested in the subject of blind babies, as the International Sunshine Society, of which I am President-General, established and maintains the only home for blind children under eight years of age in the whole State of New York. After that age they are provided for, but till then they have hitherto been kept at home, or sent to the departments for the feeble-minded. I discovered these facts in the course of my work as a newspaper woman, and with the help of interested friends started the Home for Blind Babies, at Dyker Heights, Brooklyn. In a number of cases which came under our notice, in the course of investigations, the blind children when left to themselves without occupation or amusement found both in digging their knuckles into their eyes, until, frequently, they literally picked out their eyes, and subsequently died of blood poisoning. Often sticking their fingers deep into their eyes before they could be prevented, they would squeal with pleasure, as if they experienced some agreeable sensation. I asked a physician the reason, and he said he did not know unless when the fingers were pushed in far enough a nerve was touched which gave a spark of light, corresponding to what we experience when we bump our heads and "see stars." I do not know if this is the correct explanation and shall be much interested to hear through the columns of the Medical Record the reason of this action.

Cynthia Westover Alden.

96 Fifth Avenue, New York.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PLAGUE, THE KING, VICEROY, AND INDIAN SECTION—OPINIONS OF EXPERTS—PROF. HAFFKINE'S POSITION—"KALOO" NUTS A POISON—OBITUARY.

London August 23, 1907.

On Monday it was announced that the King had addressed a letter to the Governor General of India, expressing His Majesty's anxious interest in the course of the plague epidemic, and his heartfelt sympathy with his Indian subjects. The next day we learned that a Gazette Extraordinary had been published at Simla, containing the King's letter, one from the Viceroy to the local governments, and one from the Government of India. This last states that the Plague Commission held that the disease is spread by rats, the direct vehicle being the fleas of the rats; further, that the life of the germ in the soil, floors, and walls is of short duration. Accordingly the government recommended the destruction of rats, the improvement of house construction, the reduction of the food of the rats by the care of the grain stores, the removal of people to temporary dwellings, and inoculation, while avoiding anything which would probably stir up the opposition of the natives. In a subsequent memorandum the Government of India offered further suggestions, laid stress on the inadequacy of the sanitary service for dealing with the epidemic, and recommended the creation of a special service consisting of superior officers in the Indian Medical Service, physicians sent from this country, and certain grades of natives. On consulting the local governments it was found that they all disapproved of this scheme as unsuited to Indian needs. The Plague Research Committee, which was nominated by the Royal Society and the Lister Institute, have been at work for two years, and measures have been taken to strengthen the laboratories, and the Indian Government says that every demand of the committee has been promptly met. The Secretary of State for India has sent a despatch to the Viceroy in which he refers to the above-named memoranda, urges that no effort should be spared to arrest the spread of the disease by means acceptable to the people, and adds that within reasonable limits of cost all proposals for combating the epidemic will have his support. While admitting that the Viceroy and his advisers can say with authority what measures can be enforced with good results and at what point intervention becomes dangerous, he remarks that plague having been active in India for eleven years and the number of its victims exceeding five and one-fourth millions, while its virulence is unabated and its progress uncontrolled, doubts necessarily arise as to whether everything possible has been done by the responsible authorities, and whether the last word of medical science and administrative skill has been said.

All this looks well as a defence of what has been done and as a promise for the future, but is not beyond criticism. Those who know most of the matter are not satisfied. For example, Major Ronald Ross, than whom no one is more able to speak with authority, has recently blamed the Indian Government for its inefficiency—if not worse. He recalls that the disease had been epidemic in Hong-Kong for two years before it reached India, but though this was well known no adequate measures were taken to exclude it or to detect the first cases; consequently these were unobserved, and when they had spread vacillating counsels prevailed. He seems, too, to doubt whether the great efforts since made have been made in the best way. Undoubtedly the obstruction caused by the ignorance and fears of the native population is the greatest obstacle to administrative sanitary zeal. But this obstacle does not apply to malaria, and Major R. Ross declares that it causes more sickness in India than even plague. I will add another authority—Dr. F. J. Fremantle, a late plague medical officer, has recently asserted in the *Times* that though important measures were taken by the Indian Government, they did not at first do the one thing needful—organize a thorough scientific investigation. They have now, he says, a small band of men busy in research, but that should have been the very first step. I would add it could very well have been taken while the epidemic was raging in Hong-Kong, before the invasion of India.

The position of Professor Haffkine is naturally recalled to mind whenever the subject of plague or of Indian research work is mentioned. That a great injustice was done in holding him responsible for the accidental contamination of a tetanus serum is generally admitted, and the *Times* has published a protest signed by several highly distinguished authorities. In reply to questions by Sir W. Collins in the House of Commons, the Indian Secretary, Mr. Morley, has refused to make any further inquiry, though he had to admit that Prof. Haffkine's plague prophylactic continues to be prepared at the Bombay laboratory, and that inoculation is now extensively employed without any untoward results. Mr. Morley added that he would take no action, but Mr. Haffkine would be employed in research work again if he liked to return to India, at the salary he formerly received.

In reply to another question the under Secretary for

the Colonies announced that a further grant will be made to the Liverpool School of Tropical Medicine.

"Kaloo nuts," lately imported from Africa, seem to be poisonous. Some were sold by a costermonger with grave consequences to a number of children, six of whom were treated at Guy's Hospital. The nuts were promptly seized by the police and destroyed. The seller proved that he bought them in the usual way of trade from the importer, who gave evidence that he had been in the nut trade for many years and never knew of such an occurrence. Vendors or importers can be prosecuted under the Health Acts, but it is hardly likely any more will be imported. It would be satisfactory to have the nuts identified in case of a further arrival.

Mr. Charles Williams, Senior Surgeon to the Norfolk and Norwich Hospital, and Consulting Surgeon to the County Asylums, died on the 11th inst. He contributed to the "System of Surgery" and the *Lancet* articles on stone and lithotomy, as to which the Norwich Hospital surgeons have always had much experience, stone being very prevalent in the neighborhood. Mr. Williams qualified in 1857 and in 1859 took the F.R.C.S., Edinburgh. He was a great admirer of the writings of Sir Thos. Browne, and wrote interesting articles respecting him. Among other literary essays he also wrote on the "Barber Surgeons of Norwich and the Treatment of the Sick There in the Seventeenth Century." Mr. Williams was further interested in most archæological and antiquarian subjects besides those closely connected with medical facts.

Mr. F. J. Pearse, who was Surgeon to the A Division of our police, a Surgeon Colonel in the Rifle Volunteers, and an officer in the Medical Reserve, died last week, aged 59. He had been prosector at the College of Surgeons, and took the membership in 1870. For a time he took charge of invalids on one of the steamship lines. Then he joined his father in practice in Westminster, being the fourth generation of the same family who had carried on the practice there.

The death is announced from India of Major T. W. A. Fullerton, on the 15th inst. The deceased officer graduated at the Royal Victoria Institute in 1890, and joined the Indian medical service in 1892. He was in the Waziristan expedition in 1894-5 and the operations on the Northwest Frontier, 1897-8, for each of which he was awarded the medal and clasp. In 1902 he was given the Kaisar-i-Hind Medal for Public Service in India.

Another Indian medical officer died on the 17th, Major H. F. Whitchurch, V. C., who entered the service in 1888 and was in the Lushai Expedition in 1890 and that to Chitral, 1895. It was in this last that he won the Victoria Cross by one of the most splendid deeds of gallantry, when he carried Capt. Baird to a place of safety, under constant fire from the enemy, and when nearly all the bearers had been killed or wounded. He was in the China operations in 1900, present at Peking, Peitsang, and other actions, was mentioned in despatches, and awarded the medal and clasp.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

CAUSAL TREATMENT OF SYPHILIS—CLUB PRACTICE—RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN—BUTTERMILK IN INFANT FEEDING—VITAL STATISTICS FOR 1905—LEYDEN'S RETIREMENT.

BERLIN, August 10, 1907.

As was naturally to be expected, the discovery of the pale spirochete as the specific microparasite of syphilis has given fresh life to the search for new remedies for this disease. It is well known that Bloch, several years ago, suspecting that the specific organism of syphilis was, like that of malaria, a protozoon, recommended the employment of arsenic. Lassar also had made trials, but without success, of arsenic in the treatment of syphilis, but in response to Metchnikoff's recommendation of larger doses of atoxyl (meta-arsenic-anilide) he recently repeated his experiments in this direction. He gave an injection of 0.5 gram (7½ grains) of this drug in 10 per cent. solution three times a week, and noted a speedy disappearance of the symptoms, especially in the older cases. It was remarked that the spirochetes stained especially well in preparations from cases under the arsenic treatment. Lassar believes that there is a splitting off of the anilin group of the atoxyl in the body, and that this has a selective action on the spirochete. Hoffmann has also reported three cases of severe secondary syphilides which were greatly benefited by half-gram doses of this remedy every other day. He regards the arsenic treatment as especially indicated in the severer cases.

Another "Aerztetag," the thirty-fifth, has been held. These meetings of German physicians are growing increasingly important from year to year, not only because of the great number of physicians represented in them—this year at Münster 260 delegates, representing 20,000 physicians, were present—but also on account of the importance of the questions discussed. This year, in addition to the perennial questions of club practice, other subjects discussed were the relation of physicians to the life insurance companies, quackery, and the sick relief and insurance of medical men. Objection was made to raising the limit of the income permitting membership in the medical clubs. If this limit were raised from 2,000 marks, the present figure, to 3,000 marks, as had recently been proposed, only 4.7 per cent. of the inhabitants of Saxony would be outside the associations, and free to select their own physicians.

At the eighth meeting of the Association of German Physicians, held at Münster just before the Aerztetag, the question of the relief of widows and orphans of medical men came up for discussion, and it was asserted that the sum granted them was insufficient. As, however, work is better than charity, an effort should be made, it was held, to provide them with the opportunity of earning their own living. It was determined therefore to establish a bureau, with head office in Berlin, which should obtain employment and remunerative work at home for the families of deceased physicians.

The use of buttermilk in infant feeding was discussed by Niemann recently at the Berlin Medical Society. The children to whom buttermilk was given were from three weeks to six months of age. The preparation of the food was as follows: To one liter of buttermilk were added 15 grams of wheat flour and 60 grams of cane sugar and thoroughly amalgamated by stirring; then the mixture was brought to a boil and immediately removed from the fire, and this was done four times in ten minutes; the preparation was then cooled, poured into clean bottles, and kept on ice. The buttermilk preparation was found to afford excellent nourishment for both sick and healthy babies. In 71 cases of gastroenteric catarrh complete recovery was obtained in 63. Good results were also obtained in cases of chronic dyspepsia and marasmus. Cream could be added to the mixture in any desired proportion, and the acid could be disguised by the addition of sugar. In only a few cases did the children object to the taste of the buttermilk; when they do revolt against the taste they should never be forced to take it. Cassel, in the discussion of Niemann's paper, did not approve of the employment of buttermilk regularly, but would resort to it only in cases of necessity when other food disagreed. Its use should be tentative, beginning with small quantities, and increasing as the tolerance for it was proved.

Some figures from the recently published report of health conditions during the year 1905 may be of interest. The death rate in Germany for the year was 19.8 per 1,000 living; in 1904 it was 19.5. The mortality from scarlet fever, measles, and diphtheria showed a continual decrease. In 1901 the deaths from these diseases numbered 36.52 per thousand living; in 1905 only 33.77. The birthrate was lowest in Berlin (29.9), and so also was the deathrate (16.38). The total number of deaths in 1905 was 726,670, one-third of which was of children under one year of age. Of the 28 cities having more than 100,000 inhabitants, 13 had an infant mortality above the average for the Empire, and 15 fell below the average, some of them very much below the average. The deaths from typhoid fever showed a progressive decrease, having declined from 2.04 per ten thousand living in 1877, to 0.74 in 1905. Tetanus showed a greater prevalence in Prussia than ever before; there were 4,040 cases of the disease, with 2,507 (67.2 per cent.) deaths. In 77 cases of smallpox there were 11 deaths. In 1890 28.35 per 10,000 living died of tuberculosis; in 1905 only 10.13. In man the greatest mortality from tuberculosis occurred between 40 and 50 years of age; in woman, between 15 and 30 years.

Ernst von Leyden's retirement from the Klinik of the University was made the occasion of an ovation in honor of the veteran professor. The lecture room where he had taught for so many years was filled with his students, former assistants, and fellow professors, and a large number of the medical men of Berlin. Of the many addresses we will mention only one, that of Scheide, the medical superintendent of the Charité, who

dwelt especially upon Leyden's solicitude on behalf of the patients to see that they were always made as comfortable as possible. Senator, Albert Frankel, Lazarus, and Blumenthal spoke as fellow workers with Leyden in many of his scientific undertakings, and as collaborators in the work presented to the retiring professor a volume containing many scientific contributions. Leyden himself in his reply drew a picture of the development of clinical medicine from the time of Boerhaave down to the present. He spoke especially of his teachers, Schönlein and Traube, and he expressed his gratitude to the latter in particular. In all his medical life he had always had in mind Virchow's saying, that the physician is the natural protector of the poor. With an expression of the deepest gratitude to all who were present and to those who had assisted him in those halls he bade farwell to the scene of his labors of many years.

Professor His, the former Director of the Gottingen Klinik, has been appointed Leyden's successor

Progress of Medical Science.

Boston Medical and Surgical Journal, August 29, 1907.

The Three Long-continued Fevers of New England.—Richard C. Cabot claims that there are but three long-continued fevers in New England—namely, typhoid, tuberculosis, and sepsis. But of 784 cases at the Massachusetts General Hospital, there were 586 cases of typhoid, 54 of tuberculosis, and 70 of sepsis, or 90 per cent. of the total. In summing up, he thinks it is important to realize the fact that there are but three common, long-continued fevers in New England; second, that these fevers, though often confused with each other and so unrecognized, can be recognized in the vast majority of cases provided we think of them at all and look for them carefully by the ordinary methods of physical diagnosis.

The Organization of Tuberculosis Classes.—Joseph H. Pratt tells of the work of the Emmanuel Church tuberculosis class, which was organized July 1, 1905. Since that time 54 consumptives have been members of the class, 17 have recovered and returned to work, while the disease has been arrested in 75 per cent. of the incipient and moderately advanced cases. Although it has been demonstrated that the class method furnishes an economical and efficient means of treating tuberculosis in the homes of the poor, three important points should be borne in mind if the tuberculosis classes are to be successful: First, they should be directed by physicians familiar with the details of the modern treatment, and the right woman should be selected for the position of friendly visitor. Second, there should be adequate funds for the support of the class. Third, every physician in the community should learn to recognize the disease in its early stages and to refer the case for treatment without delay.

New York Medical Journal, August 31, 1907.

Glaucoma; the Importance of Its Early Recognition.—Mary Buchanan sketches briefly the etiology, pathology, and symptoms of glaucoma. Glaucoma is divided into two forms: (1) Primary glaucoma, coming on independently of previous inflammation or traumatism, and (2) secondary glaucoma, which follows either of these and is caused by them. The direct cause is interference with filtration. The contributing causes are many. The diagnostic points in acute glaucoma are: (1) The rapid failure of sight in that eye; (2) increase in tension; (3) the dull cornea, it looks steamy, like glass than has been breathed upon; (4) anesthesia of the cornea; (5) the semidilated and non-responsive pupil; (6) shallow anterior chamber, the iris seems to be pushed aginst the cornea; (7) the lids are somewhat swollen and discolored, conjunctiva injected and swollen, and there is a red, dull, ciliary injection; (8) pain in the eyeball, reflected over the brow and temple and around the lower margin of the orbit. Having diagnosticated acute glaucoma, summon the nearest oculist, for a few hours' delay may mean blindness. While awaiting his arrival drop a one or two per cent. solution of eserine sulphate into the eye, repeating the dose every fifteen minutes until the pupil is pin-point. Use hot stupes all the time, give morphine hypodermically and a cathartic. An iridectomy is the treatment for acute glaucoma. Subacute glaucoma demands eserine sulphate and iridectomy, but the time for operation must be between the attacks.

Treatment of Chronic Indigestion.—Harry Weinstein cites a few of a long list of cases of chronic indigestion that were benefited by medical treatment. These were selected for their chronicity, with a view to illustrating that chronic cases, notwithstanding their prolonged duration, can be benefited medically. He fully recognizes the value of surgery in chronic digestive disorders, but he maintains that before recourse is had to such treatment the indications must be clear and beyond dispute. It is safer practice for the surgeon, at the present state of our knowledge of this branch of medicine, to work hand in hand with the internist, in order to better subserve the interests of the patient. Such cannot be the case if conclusions are arrived at from premises not based on actual observations and experience. Above all, an exhaustive examination is imperative in order to arrive at a proper diagnosis. The treatment of these patients is more a matter of diet and regimen than drugging.

Some Recent Ideas on Local Inflammation and Its Treatment.—Johannes H. M. A. von Tiling presents certain considerations to show why it seems natural that hyperemia by Bier's method would be most effective if used in the beginning of an inflammation, and if used prophylactically. Bier has, for instance, used the hyperemia prophylactically in cases of evidently infected wounds of the hands, where a number of finger-joints were opened and filled with dirt and most of the tendons cut, and with the best results. In cases of abscesses, where there are already many bacteria present, sufficient incisions, even if small, must not be omitted, so as not to hinder the elimination of the serum and pus that is loaded with toxins and endotoxins. He mentions this particularly, because at first, with the hyperemia treatment, the old rule *ubi pus ibi evacua* seemed somewhat negligible. On the other hand, this same endotoxin theory seems to give some counter indications for the use of the bandage. In cases of general sepsis, for instance, there is no serum in the organism which is not laden already with the products of the bacteria. Also in very virulent and very progressive infections the hyperemia treatment is, it seems, not always successful; perhaps because too many endotoxins are brought into the circulation each time the bandage is removed. Local inflammations are by no means the only affections for which the induction of hyperemia is of great advantage. Stiffened joints, joints affected by chronic rheumatism, sprains, fracture with insufficient production of callus, etc., form a large field for the treatment with either active or passive hyperemia.

Journal of the American Medical Association, September 7, 1907.

Smoke in Relation to Health.—A. Jacobi protests against the idea that the smoke question is one of social rather than sanitary importance, and quotes British and other statistics to show that diseases of the respiratory organs and their mortality have increased with the increase of the smoke nuisance in civilized communities. He quotes also experimental results of Aschoff, Schulze, Beitske, and others as proving that anthracosis of the lungs is directly caused by inhalation, and he criticises the New York sanitary code for its inefficiency as emasculated by judicial decisions, in the remedying of this evil.

Glycosuria in Its Surgical Relations.—A. E. Halstead discusses the relatinon between traumatism and certain surgical diseases and sugar in the urine. He has examined in this regard 50 cases of fracture, 6 of them fractures of the vertebræ. In three of the latter sugar was found, in two directly after the injury, one patient dying on the second and the other on the third day. The third glycosuric patient died on the twelfth day; all the non-glycosuric patients lived over two weeks. Of the remaining 44 patients, all of whom had simple fractures, six had sugar in the urine for periods of twelve or fourteen days; in none were there other signs of disturbed sugar metabolism or was the healing of the fracture influenced. These observations point to shock or cerebrospinal concussion as the principal cause of the condition. He would postpone operations that are not imperative until the disappearance of the sugar, as more permanent glycosuria might possibly result from the shock of operation or the anesthesia, and the chances of non-union be greatly increased. The secondary transitory glycosuria, due to drugs or infections, does not seem to affect the prognosis of surgical infections greatly, but it should cause the postponement of major surgical operations while the needed measures for its relief are being carried out. It is not a contra-

indication, however, to necessary minor surgical procedures, but rather the reverse. In long-continued suppuration the possibility of a secondary glycosuria becoming permanent must be kept in mind. In erysipelas, sugar in the urine is of serious prognostic moment, as an index of the severity of the infection. In diabetes, imperative operations have to be risked, and Halstead does not think that we can always take the quantity of sugar excreted as a guide to the safety of the operation. Other substances—acetone, diacetic acid, etc.—indicate a greater danger of coma than any quantity of sugar alone. He would try a thorough course of treatment, in case a high percentage of sugar is present, before performing any operation that can be postponed. Under aseptic conditions, except in the lower extremities, where the circulation is liable to be impaired, wounds heal readily in diabetes. The dangers incident to infection, however, are increased, and operations that are avoidable should not be considered. Too much stress cannot be laid on the importance of a rigid course of preliminary medical treatment. Inhalation anesthesia, even by nitrous oxide, should be avoided as far as possible. In case operation is unavoidable, ether is the least and chloroform the most harmful. Local or regional anesthesia should be the form employed whenever possible.

Corneal and Conjunctival Syphilis.—Brown Pusey reports a unique case of secondary syphilitic pustular eruption involving the cornea and bulbar conjunctiva, which rapidly cleared up under specific treatment. There was no question as to the diagnosis; the patient was also seen by a prominent dermatologist. Pusey reviews the literature of conjunctival syphilis, and shows the rarity of the condition by the fact that he could collect only twenty-seven recorded cases, though it is spoken of as not rare by Groenow. Involvement of the cornea in secondary syphilis must be even more rare, as it does not appear to be mentioned in the literature as even a possibility. Its occurrence coincident with conjunctival involvement, as in this case, would seem most likely, and Pusey had this in mind in his search of the literature.

Abdominal Pain in Relation to Ileus.—The subject of abdominal pain, especially pain in connection with ileus, is reviewed by K. G. Lennander, who refers to his former work on the subject and illustrates his points with later facts and observations. His conclusions are summarized in substance as follows: In estimating abdominal pain, and especially in connection with illnesses giving the symptoms of ileus, we must bear in mind that: 1. Pains do not originate in the abdominal organs supplied exclusively by the sympathetic fibers and the vagus. 2. All pains originate in the abdominal wall, more especially in the parietal serous membrane and subserous connective tissue structures innervated by the cerebrospinal nerves. 3. Stretching of the parietal (mesenteric) attachments of the stomach and intestines, as well as of string or band-like adhesions to the abdominal parietes, invariably causes pain. 4. The same holds true for the displacement of the parietal serosa from its normal relation to the muscles or aponeurosis of the abdominal wall. 5. Most of the diseases connected with ileus are, at their beginning, attended by increased and, as a rule, irregular peristalsis. 6. Chemically different substances, such as the contents of the stomach, intestine, etc., cause severe pain when they come in contact with the healthy or hyperemic parietal peritoneum (perforation pain). 7. Even that form of peritonitis that goes under the name of peritoneal irritation (*peritoneal Reizung*) greatly increases the sensitiveness of the parietal serous membrane. 8. The sensitiveness of the parietal peritoneum at first increases *pari passu* with the inflammation, but later decreases as the inflammation reaches a certain high degree, and may even cease altogether. (Compare herewith erysipelas, especially gangrenous erysipelas of the skin.) Lennander believes that we shall finally learn to understand completely the pains of ileus, though much still remains to be found out.

Experimental Ileus.—W. B. Cannon and F. T. Murphy report the results of experimental studies on the production of dynamic ileus which emphasize the distinction between that form due to spinal influence and that of local origin in the wall of the intestine. The animals used were cats, the method employed was to obtain by means of the x rays the peristalsis after the introduction of food mixed with bismuth subnitrate. In testing experimentally reflex dynamic ileus, the testicles or ovaries were crushed during etherization, and control experiments were made with simple etherization alone. Similar experiments were made with the splanchnic nerves cut to test the inhibitory action of these nerves. From the results tabulated, it appears that paralytic ileus can be prduced not only without mechanical changes in or about the intestinal wall, but that the condition is one of inhibition conveyed to the stomach and intestines through the splanchnic nerves. The question of local paralysis of the intestine was also studied, and it was found that manipulation of the stomach and intestine, even gently and under the most favorable conditions, had in their experiments a much greater effect in causing postoperative inactivity than any other of the factors under control during operation. After severance of the splanchnics, manipulation still produced inactivity, thus showing it to be due to local disturbance and not to extrinsic nervous influences. Certain points of practical importance, such as the location of the seat of trouble in case of intestinal paralysis, etc., are mentioned, but the authors' experiments have not progressed far enough to answer them. They have experimented with physostigmin to check reflex inhibition of the alimentary canal, and find that it had a very marked temporary effect, which was lost in about two hours. Any long-continued effects attributed to a single dose in clinical cases seem to them dubious.

The Lancet, August 24, 1907.

Pancreatitis Due to Direct Extension of a Malignant Growth of the Gall-bladder Along the Common Bile and Pancreatic Ducts.—A. W. Mayo Robson and P. J. Cammidge report a case which is clinically interesting as showing how closely cancer of the gall-bladder may simulate cholelithiasis, if the disease be associated with suppuration. The intermittency and severity of the attacks of pain for thirteen months, without jaundice, suggested the presence of gall-stones in the cystic duct, and the last severe seizure, followed by jaundice, made it appear probable that a calculus had passed into the common duct. Although no gallstones were actually found, either at the operation or later, it is quite possible that cholelithiasis may have been the original cause of the disease, and this is rendered possible by the presence of more advanced inflammatory changes in the head of the pancreas than could be accounted for by the recent invasion of the gland by malignant disease from the ducts of Wirsung. Their experience in other cases of cancer of the pancreas has shown that an inflammatory condition is apt to supervene as a complication in a certain proportion of cases, and unless this is borne in mind it may lead to errors in diagnosis and to useless operation.

Calculi in the Appendix.—D. T. Barry reports a case in which four stones, each about two millimeters in diameter, dark brown in color, smooth and faceted, composed chiefly of calcium phosphate with a small amount of organic matter, were found in the appendix. He expresses the opinion that, excluding parasites, which have been found on a few occasions, bodies in the lumen of the appendix may be classified under the following heads, which he gives in the order of frequency of their occurrence: (1) Fecal molds; (2) enteroliths, with or without a foreign body as a nucleus; (3) gallstones; and (4) true foreign bodies.

A Case of Appendicitis Excited by a Clove, the Appendix Being the Sole Viscus in a Hernial Sac.—W. Hal Barnett and J. W. Scott Macfie report the case of a man, 58 years old, who had suffered for twenty years from a rupture in the right inguinal region, which he controlled by the use of a truss. One week before admission to the hospital he found a swelling, hard and painful, which he was unable to reduce. It grew rapidly larger and painful. There was no visible impulse on coughing. The tumor was hard, elongated, and oval in shape, and about three inches by one inch in size. The mass could be traced from the internal ring down the canal as far as the testicle. At operation a small quantity of clear straw-colored fluid exuded on pricking the sac, and on further opening the mass a rough-walled cavity was laid bare containing a dark red elongated mass. Some purulent material was found, and on lifting up the red mass a clove was discovered lying beneath it. It was then realized that the tumor consisted of a short but very greatly thickened appendix lying in a hernial sac. No other viscus was found in the sac. This case was of interest, first, because of the difficulty in diagnosis, for the tumor felt almost like a malignant mass, and yet it had come down so suddenly; secondly, because of the unusual cause, a clove; and thirdly, in that the appendix, greatly thickened and inflamed, was the sole viscus in the sac.

British Medical Journal, August 24, 1907.

The Unborn Child: Its Care and Its Rights.—T. Arthur Helme says that we must recognize the rights of

the unborn child to life; to protection from the hereditary taint of degeneracy; to health—that is, to conditions conducive to the safeguarding of the health: to nature's food (when born)—that is, its mother's milk; to its natural protection (when born)—that is, its mother's care. The recognition of these rights demands the recognition of the following duties on the part of the parents, the profession, and the State: 1. On the part of the parents: A clean and normal life before and after conception. 2. On the part of the mother: (*a*) The consistent regulation of her mode of life; (*b*) the abstention from alcohol; (*c*) the feeding of the child by the breast; (*d*) the care of the child after birth. 3. On the part of the medical profession: (*a*) The restriction of therapeutic feticide; (*b*) the education of a healthy public opinion. 4. On the part of the State: (*a*) Restriction of procreation to the fit, by the regulation and restriction of marriage to the fit, either by education or legislation, and by the prevention of procreation by the unfit, whether by segregation of the unfit, or sterilization of degenerates, or the evolution of a healthy public opinion; (*b*) by regulation of the life of the pregnant woman by State provision of food for the necessitous, by provisions of hospitals for the reception of women during pregnancy, and by State prohibition of woman's work and employment during pregnancy; (*c*) immediate registration of stillbirths, premature labors, abortions, and, if practicable, pregnancies; (*d*) registration of birth within twenty-four hours; (*e*) regulation of the life of the woman who has given girth to a child by State provision of food for the necessitous, and by State prohibition of woman's work for at least six months after confinement.

Berliner klinische Wochenschrift, August 19, 1907.

The Effect of Metals on Gastric Mucosa.—Bickel found that metallic iron, metallic magnesium, metallic aluminum, metallic manganese all caused an abundant and continuous flow of gastric juice as long as they are in contact with the gastric mucosa. He explains their action by the fact that they are decomposed in the presence of a weak solution of hydrochloric acid; during this process of decomposition hydrogen is set free, which then stimulates the flow of gastric juice. The freshly secreted hydrochloric acid in turn keeps up the decomposition of the metals, and thus the process goes on until the metal is either entirely decomposed or washed out of the stomach by the increased quantity of gastric juice. That hydrogen is the real cause of the increased gastric flow is proven by the fact that metals, such as tin, bismuth, gold, and silver, which hardly give off any hydrogen when brought in contact with weak solutions of hydrochloric acid, do not increase the flow of gastric junce when put into the stomach. The knowledge of the action of metals on the stomach he considers of practical importance, since Klemperer and others use escalin (metallic iron, manganesium, and aluminum) as a substitute for bismuth in the treatment of gastric ulcer, a mode of treatment which increases the flow of hydrochloric acid when large amounts of the latter are in reality undesirable. On the other hand, these metals can be used successfully in conditions where an increase of gastric juice is wanted.

The Cause of the Absence of Phagocytosis.—Weil and Tsuda carried on extensive experiments to ascertain what could prevent test tube phagocytosis. They used only the hay bacillus, the staphylococcus, and the dysentery bacillus, all of which cause a markel phagocytosis in the presence of guinea pig serum and leucocytes. Their experiments proved (1) that this phagocytosis of the dysentery bacillus by the leucocytes was prevented when dysentery-aggressin was added; (2) that phagocytosis was absent only in the presence of the dysentery bacillus, for it took place when staphylococci and hay bacilli were added, in spite of the dysentery-aggressin, showing that the action of the latter is specific and that the aggressin does not poison the leucocytes; (3) that the absence of phagocytosis is not dependent on the absence of opsonin, for it does not take place when the bacteria exposed to the aggressin are loaded with opsonin; (4) that aggressin is the cause of the absence of phagocytosis and that it protects the bacteria in the same way as the capsule of anthrax protects it against phagocytosis.

Münchener medizinische Wochenschrift, August 13, 1907.

Spontaneous Rupture of the Rectum.—Heinecke adds the history of another case of spontaneous rupture of the rectum to the few recorded in medical literature. The patient was a man forty-five years old who for four to five years had experienced a prolapse of the rectum at stool, which he could always easily reduce. For some time he had been troubled with constipation and occasional bloody stools. The morning on which he came under Dr. Heinecke's care he was seized with a sudden tearing pain in the lower part of the abdomen while in the act of moving his bowels; at the same time a few loops of small intestine protruded from the anus. The abdominal pains, at first slight, were very intense when the patient was admitted to the hospital six hours after he first experienced them. By this time he had begun to vomit, and examination showed a rigid, distended and tender abdomen, while about one meter of small intestine with its mesentery was found protruding from the anus. The gut was dark blue in color and the mesentery was full of hemorrhages. A prolapse of the rectum was not found. After the small intenstine was thoroughly cleansed and placed into the rectum, the abdomen was opened. Some cloudy fluid was found free in the peritoneal cavity, and after exposing the rectum a tear was found in its anterior wall extending upwards for five centimeters from the bottom of the rectovesical fossa. The intestine protruding through this opening was replaced into the abdominal cavity and the latter irrigated with salt solution, after which the rectal and abdominal wounds were closed without drainage. Two days later the patient died of a septic peritonitis, which was confirmed at autopsy; the latter showed nothing else of interest outside of a loosely fixed rectum. The history of this case is similar to the majority of the twelve reported in the last eighty years. The increased intraabdominal pressure caused a prolapse of the rectum and also forced the small intestine into the blind pouch of peritoneum in front of the inverted rectum; when the pressure became too great the rectum tore and the small intestine prolapsed, while the rectum reduced itself spontaneously.

Transplantation of a Spindle-celled Sarcoma in Dogs.—Stricker, who some time ago reported successtul transplantations of round-celled sarcoma in the dog, now reports a case of transplantation of a spindle-celled sarcoma. A seven-year-old cachectic greyhound was turned over to him with the history of having had a tumor, the size of a walnut, removed from the humerus seven months previous. The growth recurred three months later and had now reached a considerable size, while metastases had developed in the axillary glands, testicle, and lungs. He removed the tumor of the humerus and the involved testicle, after which the dog lived only a month. The microscopical examination of the original tumor and all the metastatic growths showed the typical picture of a spindle-celled sarcoma. Pieces of the tumor were implanted subcutaneously in two dogs and intraperitoneally in two others. In the dogs, which had the growth implanted intraperitoneally, a laparotomy, fifty-six days later, showed numerous small fibrous nodules on the greater omentum, which, however, showed no tumor cells microscopically. The other two dogs showed a mass the size of an almond under the skin. On the forty-second day these proved to be spindle-celled sarcoma identical with the original tumor in the greyhound.

Cystitis in Nurslings.—Giuseppe Caccia considers that cystitis is comparatively frequent in nurslings, but is not usually recognized, being confounded with the effects of disturbances of digestion or other childish troubles. Its causes are various and include the same factors that produce it in adults—catheterism, infective diseases, etc. It results from fever, profuse diarrhea, cold, uricemia, arthritic diathesis, poisons, urinary stasis, and tuberculosis; from the gonococcus rarely, and from other bacterial agencies. There is one form that especially interests the author, that resulting from the presence of *Bacillus coli* in the urine. In female children these germs may be introduced from the vagina; in males when phimosis exists. In this case the infection is ascending. It is not probable that it often is of hematogenous origin and the author discards the theory of passage through the intestinal walls. The author has observed the disturbance in fifteen cases, six males and nine females. In all the males there was phimosis, and this is regarded as an important factor. The symptoms are fever, pain, nocturnal enuresis in cases in which the pain causes the urine to be withheld during the day, turbid, acid urine, containing agglutinated leucocytes and bacteria, odorless, and with small amount of albumin. The disease when not treated generally is cured spontaneously after a time, so that the prognosis is good.—*Rivista di Clinica Pediatrica.*

Book Reviews.

A Manual of Diseases of the Nose, Throat, and Ear, By E. B. Gleason, M.D., LL.D., Clinical Professor of Otology in the Medico-Chirurgical College, Philadelphia; Surgeon-in-Charge of the Nose, Throat, and Ear Department of the Northern Dispensary, etc. Philadelphia and London: W. B. Saunders Company, 1907.

This manual opens with descriptions of methods of examination in the specialties named in the title and is followed by sections devoted to detailed diseases with the proper methods of treatment. The author has condensed a vast amount of information into a comparatively small space. A considerable number of the illustrations, of which there are 262, are original or have been drawn from dissections made by the author. The latter's vast clinical experience has enabled him to produce a manual which covers all the conditions likely to be found in actual practice. The section entitled "Formulas" is more than a mere catalogue of prescriptions, as in it a detailed description of the better methods of use of each of the more important drugs has been interpolated. This is of great value to the beginner who is often overwhelmed by the large number of remedies suggested without definite directions as to their relative value.

The Essentials of Chemical Physiology. For the Use of Students. By W. D. Halliburton, M.D., LL.D., F.R.S., Fellow of the Royal College of Physicians; Professor of Physiology in Kings College, London; Author of "Text-Book of Chemical Physiology and Pathology" Sixth Edition. London: Longmans, Green & Company, 1907.

It is not difficult to understand the popularity of this work which is now appearing in new form for the sixth time. It exemplifies to a noteworthy degree the virtues of clear exposition, conciseness, and reasonable completeness, and is well adapted to the needs of both student and practitioner. In this edition such modern topics as the chemistry of the secretions and the recent advances in our knowledge of proteid metabolism have been incorporated, and the work has been brought up to date in other ways. The revision might with advantage have been extended to the appendix also, for the descriptions of the apparatus to be used in making blood examinations are not abreast of the times.

Lessons on Massage. By Margaret D. Palmer, Formerly Masseuse and Manager of the Massage Department of the London Hospital, Instructor of Massage to the Nursing Staff of the London Hospital, Member of the Council of the Incorporated Society of Trained Masseuses. Third Edition. New York: William Wood and Co., 1907.

The chief changes in this new edition are to be found in the revision of the sections on lateral curvature, flat foot, and wry neck; otherwise the book remains very much as it was before. The bulk of the work consists of such essentials of anatomy and physiology as are necessary for the intelligent application of massage. The remainder treats of massage in general, massage of special regions, and massage of children. There are chapters on the Nauheim or Schott treatment and on bandaging; and the book concludes with a fairly complete glossary. The volume is clearly written, is well illustrated, handy in size, attractive in appearance, and will prove useful to nurses and masseuses.

Atlas and Textbook of Dentistry, Including Diseases of the Mouth. By Gustav Preiswerk, M.D., Ph.D., of the University of Basel. Authorized Translation from the German. Edited by George W. Warren, A.M., D.D.S., Professor of Principles and Practice of Operative Dentistry, Pennsylvania College of Dental Surgery. With 103 colored figures on 44 plates and 152 text illustrations. Philadelphia and London: W. B. Saunders Company, 1906.

This volume is the latest addition to the English translations of Lehmann's well known medical hand atlases. Most of the present volume is of interest only to dentists; but the chapters on the anatomy, bacteriology, histology, and embryology of the teeth, and on diseases of the mouth will appeal to the medical practitioner. Naturally the illustrations form the chief part of the work, these are both artistic and instructive. The reading matter is probably a fair presentation of dental practice in Germany.

Short Medicine. By John Godfrey, Surgeon P.H. and M.H.S., Detroit, Mich. The Rebman Co. and Baker Co., Printers, 1907.

This is a volume of verses composed by a surgeon of the Public Health and Marine Hospital Service and dedicated to the Medical Officers of that service. Like Burton, the author undertakes "things unattempted yet in prose or rhyme." But here everything Miltonic ends; we quote a stanza, taken at random:

> "Why his abdomen failed to crack
> Is almost a conundrum,
> For there was not an empty space
> In even his jejunum."

It would certainly be cruel to prescribe this volume for any patient, even in homeopathic doses; but possibly it was only intended by its author for the amusement of his brother practitioners.

Diagnosis of Organic Nervous Diseases. By Christian A. Herter, M.D., Professor of Pharmacology and Therapeutics at Columbia University; Visiting Physician to the City Hospital. Revised and Enlarged by L. Pierce Clark, M.D., Visiting Neurologist to the Randall's Island Hospital and Schools; Consulting Neurologist at the Manhattan State Hospital, N. Y.; Consulting Neurologist at the Craig Colony for Epileptics, Sonyea, N. Y.; Assistant Neurologist at Vanderbilt Clinic (Columbia College), New York. With 109 illustrations. New York and London: G. P. Putnam's Sons, 1907.

In the new edition of this book the chapters on the anatomy and physiology of the nervous system and on the examination of the patient have been largely rewritten, and the section dealing with the symptomatology of nervous diseases has been modernized. The scope and general plan of the work remain as before. In its new dress this volume is probably the most useful book on the diagnosis of nervous diseases that could be put into the hands of either student or general practitioner. While professing to be elementary in character, it gives enough detail to make it entirely serviceable and satisfactory. The authors have been eminently successful in making attractive a subject that is generally disliked by the average student. The only adverse criticism we have to make is on the inaccuracy of many of the references.

Hints on the Management of the Commoner Infections. By R. W. Marsden, M.D., M.R.C.P., D.P.H., Honorary Physician to the Ancoats Hospital, Manchester; Honorary Assistant Physician to the Manchester Hospital for Consumption; Formerly Medical Superintendent Monsall Fever Hospital, and Clinical Lecturer in Infectious Diseases, Owens College. New York: E. B. Treat & Co., 1907.

In most books dealing with the practice of medicine the discussion of treatment is generally brief and often vague. Quite frequently the seeker after therapeutic knowledge is told to "attend to hygiene," or to "reduce the temperature," or to "treat symptoms," or something else equally indefinite. The present volume gives in some detail the general principles of treatment that are to be observed in the management of the more commonly occurring infectious diseases. The introductory chapter contains general measures, such as methods of applying cold water to the skin, contraindications to cold baths, stimulation, importance of rest, details of the bed and bedding, ventilation, cleanliness, warmth, feeding, details of nasal feeding, alcohol, etc. Then follow separate sections on the treatment and hygienic indications in the different specific diseases. The book concludes with valuable chapters on isolation and disinfection. The volume contains just the information that the student and young practitioner are apt to require; and the book will serve as a useful companion to any textbook on practice or therapeutics.

American Pocket Medical Dictionary. Edited by W. A. Newman Dorland, A.M., M.D., Assistant Obstetrician to the Hospital of the University of Pennsylvania; Fellow of the American Academy of Medicine, etc. Containing the Pronunciation and Definitions of all the Principal Terms Used in Medicine and the Kindred Sciences, Along with Over Sixty Extensive Tables. Fifth Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders Company, 1907.

This is apparently a condensation of the editor's larger dictionary and has the defects of all such abbreviations in that the ideas of the editor and the consultor seldom coincide, the editor often leaving out much that the consultor wants to know. For example, there is no definition of opsonic index, of Mendel's law, of heart-block, of *Treponema pallidum*, or of many other modern terms. Perhaps the apparent fact that this is not a new edition, but only a reprint, may explain some of these omissions. We have been unable to verify the statement on the title page that the book contains over sixty extensive tables; most of the so-called "extensive tables" are merely a few subtitles grouped under the main title. We do not think the editor's reputation as a dictionary maker will be enhanced by this book.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twenty-ninth Annual Meeting, Held at Washington, D. C., May 7, 8, and 9, 1907, in Connection with the Seventh Triennial Congress of American Physicians and Surgeons.

Special Report to the MEDICAL RECORD.

Tuesday, May 7—First Day.

DR. A. W. DE ROALDES OF NEW ORLEANS, LA., PRESIDENT.

President's Address.—Dr. A. W. de ROALDES thanked the Association for the honor it had conferred upon him and alluded to his own work in the establishment of the Hospital for Eye, Ear, Nose, and Throat diseases in his own city. He felt that it was the Association's duty to push the work of securing for the specialty a greater recognition than it yet enjoyed in the medical schools and that a further need of the times was the establishment of more special hospitals for this class of diseases. This would not at all interfere with special departments in general institutions. He also announced his intention to establish a prize fund for the Association. This suggestion had been made many years ago by the Association's first president, the late Dr. Louis Elsberg. He referred to the deaths of Señor Manual Garcia, Honorary Fellow, and of Dr. William Carr Glasgow, Active Fellow, both of whom had died since the last meeting. He also referred to the celebration of Prof. von Schroetter's seventieth birthday in Vienna, to the similar celebration in honor of Prof. Bernhard Fraenkel in Berlin, the pleasure felt in welcoming Prof. Gustav Killian of Freiburg to the present Congress, and the proposed Tuerck-Czermak Congress to be held next spring in Vienna to celebrate the semi-centennial of the establishment of systematic teaching in laryngology.

Tuberculosis of the Accessory Sinuses of the Nose.—Dr. J. W. GLEITSMANN of New York read this paper, which was in the main an analysis of the recorded cases. The majority of instances of sinus tuberculosis were referable to extension from some adjoining focus. In twenty antral cases tuberculosis of the bones of the nose or of the upper maxilla was found twelve times. The majority had pulmonary disease and only a few had the local disturbances of antral disease without constitutional symptoms, but at operation tubercle bacilli were found in the antral contents. In eight the bacilli were found in the external discharge. Tubercle of other sinuses must be rare, the author said, as he had found records of only four cases of frontal disease and one of combined ethmoidal and sphenoidal disease. Pathological changes were very much the same as in nasal tubercle. Empyema, exuberant granulations, caries, cheesy deposits, all were found, while examination of the sinus lining showed exfoliation of epithelium, extensive smalled-celled infiltration, penetrating the superficial as well as the deep layers of the mucosa, while the middle strata had revealed the fibrous structure of the connective tissue containing serous liquid and some leucocytes. Efferent glandular ducts and their lumina had been enlarged, giving rise to cystic spaces, and giant cells had been found in the infiltrated tissue. Of the entire number only three cases showed confinement of the tuberculous process to the antrum, viz., the cases of Coakley, Gaudier, and Keckwick. Dr. Gleitsmann gave summarized clinical histories of some of the more important cases. Prognosis must be regarded as unfavorable. Treatment was eminently surgical and did not differ from that generally adopted in severe cases of sinus disease. It naturally had to be more radical, as not alone the soft parts, but all diseased bone had to be removed.

Dr. C. G. COAKLEY of New York gave some additional facts as to his own patient whose case was referred to by Dr. Gleitsmann. This patient had been under observation for over two and a half years and when last seen had no evidence of the disease in any other part of the body. Diagnosis was positive in this case as giant cells containing tubercle bacilli had been found in the tissue removed from the antrum.

Prof. GUSTAV KILLIAN of Freiburg, a guest of the Association, stated that he had had a case of multiple tuberculosis of the bones with caries of the left frontal sinus. Operation was followed by recurrence of the sinus condition. There was tuberculosis of the maxillary bone and of part of the antral walls, but no pus. Tubercles were found in the mucosa of the frontal sinus.

Dr. HARRIS P. MOSHER of Boston referred to a low grade of tuberculosis, a scleritis which had defied treatment. Finally the use of tuberculin determined its nature. Dr. Mosher had recently been giving tuberculin in certain sinus cases, but thus far had obtained no reaction. In the ordinary forms of tuberculosis in sinuses it was difficult to find bacilli. He would not consider tuberculin as of much value in these cases as compared with the usual methods of surgical intervention. Dr. Gleitsmann, in closing, referred to the work of Bartles, who had endeavored to formulate the condition known as the tuberculous state, declaring that before this period arrived there was a pretuberculous epoch manifesting itself mainly in lymphoid infiltration, a hydremia of the parts involving the lymphoid tissue similar to the hydremia observed in septic cases before real septic symptoms manifested themselves.

Massage of the Pharynx.—Dr. SAMUEL W. LANGMAID of Boston exhibited an instrument which had been devised for the purpose named by an eminent tragedian, the late Edwin Forrest. This instrument was a smooth wooden handle with curved ends which Forrest was accustomed to sweep around in his throat in order to "ream out the old trumpet," as he expressed it. It had been impossible for various reasons to discuss with the actor the latter's views as to the value of the manipulations referred to. Dr. Langmaid had long been accustomed to recommend to his patients massage of the throat by some such implement as the broad, rounded extremity of a tooth brush handle. It greatly reduced the irritability of the pharynx, removed enlarged follicles on the posterior wall, and in general seemed to reduce hyperemia. Since writing his paper he had found that a century ago a certain British Admiral, who wrote more as an osteopathist than as a masseur, recommended instrumental massage of the mouth and throat not only as a prophylactic measure, but as curative also for sore throat.

Dr. J. SOLIS-COHEN of Philadelphia stated that he had often used the so-called extension finger of the dentists in pharyngeal manipulation so as to accustom patients to the handling of the epiglottis.

Dr. G. HUDSON-MAKUEN of Philadelphia believed that in these cases much could be done in showing the patient how to keep quiet during examination by having him manipulate the pharynx with the handle of a tooth-brush or similar instrument. The patient's' attitude was too often one of self-protection rather than of cooperation, and he should be taught to give the physician intelligent assistance. Dr. Makuen could not agree with a statement Dr. Langmaid had made that singers and speakers had anemic pharynges.

Dr. CLARENCE C. RICE of New York was inclined to agree on this point with Dr. Langmaid. In his experience noted singers and actors did not, as a rule, have much chronic pathological change in their throats. His own feeling was that the strong use of the voice and vibratory massage of the pharynx tended to atrophy and anemia rather than to congestion. If he found congestion in a singer's pharynx without any special nasal or postnasal catarrh he would ascribe it to tobacco or alcohol rather than to voice use. In general, intelligent massage was a useful therapeutic measure.

Bilateral Abductor Paralysis of the Larynx.—Dr.

Charles H. Knight of New York reported a case of this nature. He thought the lesion referred to was more common than authorities would lead us to believe. It was often difficult to distinguish between abductor paralysis, abductor spasm, and ankylosis of the cricoarytenoid articulation, and prolonged observation was often required in determining the actual condition in a given case. The author passed in review the differential features diagnostic in the conditions named and then reported the case of a middle aged man of nervous temperament who in childhood had had chorea and had been subjected to severe nervous strain. He had been alcoholic for one year, some years before coming under notice. Six years ago he had an attack of ptomain poisoning. The year following he suffered increasingly from rapid heart action, dyspnea, and vertigo. Later he developed sciatica, presumed to be the forerunner of tabes. Six years ago he contracted syphilis and had the usual secondary symptoms, but received thorough treatment. One year ago he was suddenly awakened one night struggling for breath. Later, when running for a train, he had his first attack of laryngeal spasm. During the last six months he had had some twelve or fourteen repetitions of this spasm, all but one or two coming on during sleep. Sometimes the attacks had followed excitement or exertion. After exercise there was always inspiratory stridor. The laryngeal image was typical of bilateral paralysis of the abductors, with a moderate grade of catarrhal inflammation. A redundant uvula was excised, inhalations of mentholized oil given with strychnine and iodide of potassium. Electricity seemed to aggravate the symptoms. Under the foregoing régime there had been some improvement. The author referred to the following proposed measures in such cases: (1) Intubation, (2) ablation of the soft parts lining the voice box, (3) division or resection of the inferior laryngeal nerve, and (4) tracheotomy. His personal experience had been limited to the first and last. In this particular case one observer who had previously seen the patient urged immediate tracheotomy, but this was refused by the patient, who preferred death to wearing a tube. Dr. Knight thought that up to the present time at least the result seemed to have justified this decision. He considered that in such cases the ideal procedure, on theoretical grounds at least, was resection of one recurrent nerve, whereby the corresponding vocal band would be placed in the cadaveric position and the voice would finally be regained through compensating action of the abductors of the opposite side. He had been unable, however, to find any successful record of such a case. Mere division of the nerve was useless, as it was possible that in some of these cases a portion of the innervation of the abductors was derived from the nerve of the opposite side and in addition there might be more or less ankylosis of the cricoarytenoid joint. Tracheotomy would doubtless afford us the most satisfaction. It was best done under local anesthesia. The onset of dyspnea was often alarmingly sudden. The prognosis in such cases was less hopeless than was generally believed.

Removal of Papillomata of the Larynx by Direct Instrumentation with the Aid of Killian's Tubes.—Dr. Cornelius G. Coakley presented a paper reporting six cases of this nature and discussing the general mechanical problems involved. He had tried the Kirstein method of examination years ago, but had given it up. Observing at Killian's clinic, however, the case with which bronchoscope tubes were passed through the larynx, it occurred to him that such a tube with a window on one side could be used for the removal of laryngeal papillomata. He had had opportunity to give the method a trial in six cases. In all a general anesthetic was used. Some time might be saved by cocainizing the pharynx and larynx before the administration of the anesthetic. The patient should be placed on the back, the shoulders brought to the edge of the table, and, supported by an assistant, allowed to hang over. The operator should sit on a low stool, the height of which could be so adjusted that the eye was directly opposite the widely opened mouth. The tongue should be grasped with forceps and drawn out, thus raising the epiglottis and facilitating the introduction of the spatula beyond the tip of the epiglottis. The tongue was now allowed to fall back into the mouth and the spatula was easily passed directly into the supraglottic portion of the larynx. A good view of the cords was now readily obtained, and any growth thereon could easily be removed by a straight forceps passed through the spatula. The Kirstein headlight had been the illuminating agent. It had been somewhat difficult to remove multiple neoplasms on account of obscuration of the field by blood and mucus in spite of frequent wiping away with cotton. Out of the six cases the result was satisfactory in four. One proved to be malignant and required a thyrotomy, while in one the bulk of the growth appeared to be caught between the spatula and the anterior portion of the larynx.

Prof. Gustav Killian said that he had two cases under observation in which he had operated in the method described by Dr. Coakley. In such cases it was necessary to cocainize the larynx very thoroughly or it would contract from the contact of the tubes so that nothing could be seen. This method obviated laryngotomy and tracheotomy. If the patient could breathe sufficiently well to allow of general narcosis, the direct method of operating might be employed. In recurring cases arsenic should be given for a long time. Potassium iodide also seemed to have some power in preventing the recurrence of papillomata.

Dr. E. Fletcher Ingals of Chicago had had several successful cases by the direct method. In one case during operation the larynx began to close, the child could not breathe, so he had to do a quick tracheotomy, as he had no intubation tube. In general, he was inclined to believe that tracheotomy was best in all cases in young children, though Dr. Coakley's experience had demonstrated the fact that it was not necessary.

Dr. J. Payson Clark of Boston referred to a paper on this general subject presented by him to the Association some years ago and gave the later history of some of the cases therein referred to. He had used the direct method in removing the growths. He was still a partisan of tracheotomy, as it gave the larynx perfect rest, during which a papilloma was more likely to atrophy than when the child was using the larynx as a respiratory organ.

Dr. Emil Mayer of New York spoke of some of the disadvantages of the tube with reference to the heat from the headlight. The attachment of the light to the handle of the spatula was a great improvement. His own experience as to recurrence had been the same as that of the preceding speakers.

The paper was further discussed by Drs. H. L. Swain, Casselberry, Goolidge, Lincoln, Langmaid, Hubbard, Delavan, and Ingersoll.

Dr. Coakley, in closing, stated his belief that cases of recurrence in children were cases in which new papillomatous areas occurred. Such would crop up in spite of all one could do. He certainly would not consider any cases as cured unless there was a freedom from return of the growth for several months. He believed, however, that if these cases were seen early it was often possible to avoid the deformity of an external operation, but one should not give an anesthetic without having a tracheotomy tube handy. He preferred to apply ten per cent. cocaine before the general anesthetic was given, waiting sufficiently for the cocaine to act. He was not sure of the efficacy of pure carbolic applications to the seat of the growths. It was at least harmless, but he would not use it unless the patient was wearing a tube. He had used cocaine in connection with chloroform several times without had re-

sults. He knew, however, that such a combination was regarded by some as risky. A tracheotomy tube, if worn some years, would be likely to produce a certain amount of stricture, though this might cause no trouble. Parents were naturally averse to having scars on their children's neck, especially with girls. On the other hand, tracheotomy was distinctly of service in giving rest to the larynx.

Ophthalmological Manifestations of Latent Disease of the Nose and Its Accessory Sinuses.—Dr. Francis R. Packard of Philadelphia reported a series of cases illustrating the relation between eye and nose conditions as suggested by the title of his paper. The examinations of the eyes had been made by Dr. W. C. Posey of Philadelphia. Dr. Packard stated his belief that there should be more active correlation between the ophthalmologist and rhinologist in order to insure the recognition of this class of cases. Experience had shown that the ocular symptoms occurring as a result of sinus disease might variously affect the vision and visual field, orbit, lacrymal apparatus, lids, extraocular muscles, conjunctiva, cornea, pupil, and uveal tract, and might lead to cataract, reflections, asthenopia, and headaches and neuralgias. His series of nine cases reported bore out the foregoing statements. The truth of this theory of connection between the two organs was borne out by the results of treatment. Dr. Packard referred to various contributions on the subject by various authors.

Dr. J. H. Bryan of Washington, D. C., had for some time been accustomed to have his sinus cases examined by an oculist and had seen external rectus paralysis from sphenoid disease, scotoma, narrowing of the visual field, etc.

Dr. G. A. Leland of Boston stated that there were three cardinal symptoms of the eye condition that pointed directly to an intranasal origin, namely, astigmatism against the rule, ciliary reflex, and narrowing of the color field. He gave the detailed history of one case of the nature described in Dr. Packard's paper.

Dr. L. A. Coffin of New York said that the connection between eye and nose conditions was not yet sufficiently recognized even in special institutions. Patients operated on for sinus disease were often able to lay aside their glasses.

Dr. F. C. Cobb of Boston said that in sinus disease conjunctivitis might arise from direct infection from nose to eye, but with regard to astigmatic affections there was little satisfactory evidence. There was a tremendous neurasthenic element in all these patients, and allowance ought to be made for this before we made positive statements as to the relations between the maladies of the two organs in question.

Dr. H. P. Mosher thought ptosis a rather unusual symptom of latent frontal sinus disease. He had, however, seen it once. He had come to the conclusion that the *x*-ray would clear up many cases of weakness of vision due to trouble in the sinuses or ethmoidal region. An ethmoidal condition might be revealed which had given no signs in the nose.

(*To be continued.*)

AMERICAN ACADEMY OF MEDICINE.

Fifty-second Annual Meeting, Held at Atlantic City. June 1 and 3, 1907.

(Special Report to the Medical Record.)

Saturday, June 1—First Day.

The President, Dr. Casey A. Wood of Chicago, in the Chair.

Report of the Committee to Investigate the Value of the First Degree in American Colleges. "The Academic Training for Medicine."—Some points presented in the report were: The faulty curriculum of the medical school; the time element; the plans for condensation or shortening. The difficulties in the way of coordination of secondary, collegiate, and technical education were stated. An outline course was suggested, involving changes in each class of schools. To make the suggestions effective the committee recommended that the Academy hold a meeting for the full discussion of the problems, to which representatives of educational institutions be invited for a full discussion of the subject; that an outline program be presented at this meeting, and, that the American Academy of Medicine act as a central bureau to give efficiency to the conclusions of the conference.

The Communal Life of Physicians; Its Cultivation and Value.—Dr. Leartus Connor of Detroit in presenting this paper defined the "Communal Life of Physicians," outlined methods for its cultivation, and presented estimates of its values under the following heads: 1. The individual physician. 2. Physicians as a unit. 3. Physicians outside communal life. 4. The laity. 5. Medical science and art. It was shown that individual growth, professional development, and medical triumphs awaited a clearer perception and unswerving obedience to the obligations of the communal life of physicians.

The Superiority of the Playground to the Schoolroom.—Dr. Woods Hutchinson of New York City thought the superiority of the playground over the schoolroom in the physical development of the child needed little proof. In addition to the disadvantages of the overheated air of the schoolroom, inadequate ventilation, and improper light, the child was denied his divine right to wriggle. Children kept out of school for half the day were said to make better progress in their studies alone, to say nothing of the improved physical and mental condition. That the child would never learn the classics in the school of play was regarded one of its chief advantages. These, the author said, represented a relic of barbarism, of caste education, of culture separating its possessor from the rest of his kind, the aim of which was selfish in self-culture and personal exaltation. The aim of modern scientific education was rather effectiveness for helpfulness to others. The playground was claimed to be equally effective on the moral side by checking and controlling the child's impulses and interests through contact with his fellows. The best morality in the world he thought was to be acquired on the playground. Justice and fearlessness rather than charity were said to be demanded by the new code.

Dr. Winfield S. Hall thought many of the principles expressed by Dr. Hutchinson were recognized by the present day educators. He recalled the case of a girl of fourteen brought up on the plains who had shown remarkable development after being in school one year. This larger ability to study was also marked in boys able to attend school for only three months in the year. Even in the playground, however, he would have the attention of the children riveted as an aid in their mental development.

Dr. J. W. Grosvenor of Buffalo agreed in part with Dr. Hutchinson, but was entirely opposed to the idea that a child should follow his own sweet will. Because of his belief in the matter of heredity concerning the mental and moral characteristics of the child he said education should be largely individual. Even the play of the child should be superintended by an experienced person. The study of the classics he regarded of advantage in the training of the mind, especially of the memory. He agreed with Dr. Hutchinson, however, that too much time was spent in the schoolroom.

Dr. S. A. Knopf of New York City would not have children enter school before the seventh or eighth year and would have the first few years made up of half or three-quarters play. He suggested the advantage of having singing and recitations out of doors, and in this connection referred to the custom in the German army of allow-

ing the soldiers to sing while on march. He thought physicians should urge the establishing of roof gardens in school houses when land was not available.

Dr. Ernest B. Hoag of Pasadena spoke of the admirable results in education obtained at the Theosophists' colony at Point Loma, California. The children were not in school more than two hours a day. They were divided into groups, each group having a teacher. Their play was so superintended as to be instructive. Hygiene was taught by making it a part of their life. Dr. Hoag was careful to state that while admiring the methods of education at the colony he was not a theosophist.

Dr. Emma B. Culbertson of Boston agreed with Dr. Hutchinson in protesting against the faddism of the modern schools, feeling that they were going to great extremes. She thought the great trouble before the public schools lay in the overindulgent method of the kindergarten. To her mind a kindergarten child was a child spoiled to study. She felt strongly that the study of Latin was a necessary foundation for the study of all other languages and a necessity for an accurate application of language to the expression of ideas. Personally she felt that she was a better physician, a better woman for this study.

Dr. M. G. Motter of Washington, D. C., was glad to hear the defence of the classics which he thought an absolute necessity in the preliminary training of physicians. In the present day system of public school education he felt there was too much instruction and not enough education.

Dr. Leartus Connor of Detroit spoke in defence of the study of Latin and Greek.

Dr. Edward Jackson of Denver said that the great supremacy of the playground over the schoolroom lay in the great value of spontaneous action on the part of the child. Illustrative of this he contrasted spontaneous muscular movement to movement in obedience to external influence. There might be, however, schools and teachers capable of giving all the advantage of that spontaneous effort by which the child is benefited in the playground. A principle of importance in the education of a child was the recognition of a certain need or the existence of a special aptitude, either natural, or acquired from teachers who had presented attractively studies in which they themselves were especially proficient. As in the girl of fourteen mentioned by Dr. Hall, she acquired easily that which she saw in others and desired. He felt that the importance of the child doing what he wanted to do should be recognized.

Dr. Thomas D. Davis of Pittsburg, who had been for more than twenty-five years on one of the school boards which he said were berated so continually, was anxious for practical information from any source. He had tried to carry out the so-called advanced ideas with the result that the school children were older when prepared for the high school than formerly. He took strong exception to Dr. Jackson's idea that children should be educated according to their natural bent, believing that if they were trained in the line of least resistance they would be narrow minded. If it were found that the playground would give the child a better all round preparation for life than the schoolroom he thought it well to get rid of the schoolroom.

Dr. Donly C. Hawley of Burlington, Vt., thought it true that to-day children were educated too much—not too well. He believed it better for the child to enter school later, probably at ten years and thought the time would come when half day sessions only would be held. Those not taking up a professional life he thought should not remain in school so many years as was the present custom. All children he thought should not study the classics, but agreed with Dr. Culbertson that the study brought the scholar in touch with the best thoughts of the best minds. Mathematics should be especially taught to the boy or girl who did not like them. Such child not having a logical mind would thus be developed in this trend of thought. He regarded the playground important in the child's education in putting him in touch with nature and with his kind, but did not believe in the extreme degree of the principle as presented by the author. He regarded it rather as a valuable accessory to the school.

Dr. Hutchinson, in closing, referred to instances in which the children kept out of school for two or three years or kept on half time had made the same progress as those in constant attendance. He asserted that the best pedagogical practice was in favor of giving the children an opportunity to grow up according to their natural tendencies. For those who liked the classics he would favor their study, but he would not compel every student to come up against this Chinese wall. He acknowledged the value of the study in its bearing upon the history of the ancients, but emphasized his belief that it tended to keep alive the desire for education, not for the sake of usefulness to others, but for the sake of self-culture and a certain air of distinction, an aim in his opinion purely selfish and opposed to the aim of science in its service to humanity.

The Social Education of the Child.—Dr. A. L. Benedict of Buffalo asserted that every child who was not defective should attend the public schools. He would not advise higher education unless the individual was liable to need it. The economic disadvantages of too high education for too great a proportion of the population were pointed out. What were called class distinctions he would have recognized to some degree. Important in the social education of the child the following items were mentioned: The avoidance of jealousies; the effort to change oneself rather than the world; care not to make principles out of prejudices; the greeting and entertaining of all acquaintances as if it were a pleasure to meet them, or else the avoidance of them altogether; the elimination from one's acquaintance of the low, selfish, demoralizing, unreasonable, and troublesome; the repayment of every debt, social as well as financial; the realization that being square is an important item in social success.

Insurance for Defectives.—Dr. James A. Spalding of Portland, Me., having been refused renewal of an accident policy, investigated the topic especially from the position of those who were like himself, deaf. He discovered that those who hear run many risks apparently more dangerous than those who are deaf. He found that many accidents occurred to all persons alike, and that in railroad accidents especially all were liable to serious accidents. For that reason, among others, the deaf and other defectives ought to have an adjustable insurance covering such accidents as were liable to all, and excluding special classes of accidents. Just as some companies asked higher rates for the syphilitic, in certain stages, so accident insurance should be more carefully overhauled, and better provision be made for the defectives. Standards should be set for a proper insurance both for accident and for life by going into the minute defects rather than into so many family defects which might be called gross.

Dr. James Evelyn Pilcher agreed with Dr. Spalding that defectives more than compensate for their lack in the added care taken, or in the added excitation of some other sense. He did not think it necessary that there should be an extra premium for the insurance of defectives, but could such insurance not be obtained otherwise, he thought a movement in this direction should be started.

The Soldier as a Total Abstainer from Alcoholic Beverages.—Dr. J. W. Grosvenor of Buffalo described what the soldier ought to be and dwelt upon his work and his needs. He should be a high type of man physically, mentally, and morally. Patriotism should stand out in all his military career. Reference was made to his clothing, recreation, and amusement. His pay should be adequate to furnish him largely with the comforts and conveniences which would be his in civil life, together with a pension for disability or old age. To the question whether or not the soldier needed alcoholic beverages it was stated that

science and experience give an emphatic negative. All scientists who had studied the qualities of alcohol and its effects on the human system declared in unequivocal terms that it had no utility in the development of the health of the human organism. Many quotations of scientists were given to this effect, among which was the statement of Kraepelin and Kurz, who have shown that "one ounce of alcohol diminishes the acuteness of all the special senses—sight hearing, touch, taste, and smell, and also retards the mental processes of reason, judgment, or sense of propriety, and memory." Equally convincing were the arguments shown against the therapeutic value of alcohol to the soldier. N. S. Davis, Sr., was quoted as saying that "step by step the progress of science had nullified every theory on which the physician administered alcohol." The writer was confident that not until total abstinence from alcoholic beverages had become the controlling rule in all departments of the army would there exist that freedom from drunkenness, desertion, crime, vicious habits, sickness, and inefficiency which should characterize the defenders of a republic whose rulers were its citizens, and who had a right to demand from the soldiers the highest efficiency and patriotic devotion.

Dr. James Evelyn Pilcher, from experience in medical service, during which time many thousand soldiers passed under his personal supervision, could say that the statements made in the paper were correct, asserting that there was absolutely no question, other things being equal, that the soldier who was a total abstainer was infinitely more efficient than the soldier who was in the habit of taking alcoholic stimulants. He paid a tribute to the American soldiers, the great majority of whom he said were beyond criticism in their general conduct. Among the officers the number of total abstainers was said to be very large.

Dr. Winfield S. Hall remarked that the statement concerning the small number of army officers who drank heavily was in harmony with the decrease in drinking among the other professions. In times past it had not been an uncommon thing for the family physician to be a heavy drinker and still maintain his position in the profession. The education of the public and of the profession at the present day, however, would not tolerate this.

Dr. John Chase of Denver spoke of the great difficulty encountered by men desiring to enlist in the National Guards of Colorado if they were users of alcohol. The utmost care was taken to exclude such men and the result was shown in the great enduring power of the guards, the men having been at times on duty for seventy-two hours without sleep. It had been found that the men did better by drinking tea than alcohol.

Dr. Leartus Connor believed that most men drank when they desired to forget some unpleasant experience or condition and that the conditions of life of the United States soldier tended to make him seek this forgetfulness. If the army were made a desirable place in which a man could serve his country he did not believe drinking would be largely indulged in.

Dr. James A. Spalding of Portland, Me., spoke of the effort of the Sturgis law in compelling the sheriff to enforce the prohibition law, the result of which was to bring about the pocket peddling of liquor. On one occasion an officer had found thirty per cent. of his men in the hospital from the cocaine habit. They had gone over the town and, not being able to get a little beer and because they did not want to drink bad rum, they had used cocaine. He questioned whether in taking away alcohol good would be done if cocaine were substituted.

Dr. Woods Hutchinson was in accord with much of the paper, but thought one point to be challenged was the statement that all medical men and scientists were in accord upon the uselessness of alcohol in health and disease, believing that the facts in the case did not support the statement. He asked why men drank. The normal man, he claimed, did not take alcohol as a food, but as a means of enjoyment. The Scriptures stated long ago why it was that men drank. The injunction of St. Paul to the youthful Timothy had been: "Drink no longer water, but use a little wine for thy stomach's sake and thine often infirmities." Again it was said: "Give strong drink to him that is ready to perish, and wine unto those that be of heavy hearts. Let him drink, and forget his poverty, and remember his misery no more." So long as conditions were unfavorable, so long as men were subjected to injustice, were placed under conditions of hardship, so long, Dr. Hutchinson believed, they would continue to resort to alcohol. This he thought was the aspect of which Dr. Grosvenor had not treated. This, he reasoned, was an argument for the retention of the canteen, for with the canteen alcohol was taken within certain limits and the opportunity was not offered for the soldiers to secure bad liquor.

Dr. Grosvenor, in closing, admitted that undoubtedly there were two sides of the question, stating that some people occupied one side, some people the other side. He firmly believed that he was on the right side, that many people were with him, and that more were coming than a few years ago. He thought all would agree that the better educated, especially the medical profession and the clergy, were coming to the opinion that total abstinence was the right thing for all normal individuals, for all who were sick, and the way to keep people from crime, immorality, and vicious habits, to a very large extent. He believed that the total abstinence opinion was growing in the country. He regarded Dr. Hutchinson's criticisms as not in accord with the tone of progress in his own paper of the morning, and urged that he come up onto the modern platform of the present day, the platform which was rising higher and higher, and in support of which Dr. Hutchinson could give valuable assistance.

Monday, June 3—Second Day.

A Medical Career and the Intellectual Life.—Dr. Casey A. Wood of Chicago took this topic as the subject of his Presidential Address. The most conspicuous want of the medical practitioner was said to be a useful and pleasure-giving recreation. What that particular form of occupation should be might well vary with the individual, but that it should be instructive—perhaps unconsciously instructive—seemed self-evident. Sir John Herschel was quoted in his eloquent estimate of the advantages of literary pursuit, saying that in books were found solace, refinement, and recreation. The physician, however, it was felt must have a feeling of unrest who was not engaged, even during his recreation, in work likely to add to the sum total of human knowledge. To meet this condition the pursuit of some branch of the natural sciences as the desirable recreation of the practitioner of medicine was advocated, and a plea made for the adoption of what might be called the "outdoor" sciences as the most useful and most valuable of all the recreations. The close relation between the natural sciences and the study and practice of medicine was briefly mentioned. Comparison was made of the values of investigations of science, and mere book learning and reference made to Herbert Spencer's essay on "Education," and to the "Lower Geology" of Rev. Charles Kingsley, whose name was dear to those who loved science, revered literature, and respected religion, because he lived them all in one fair life. Spencer in an endeavor to answer the query, "What knowledge is of most worth," believed it might be answered by an appeal to conduct tempered by knowledge and showed the conditions to be filled to a very large degree by a careful study of the natural sciences. All of the outdoor sciences were not enumerated, brief mention being made of botany, with its many subdivisions into agriculture, floriculture, arboriculture, forestry, etc.,

as offering a most varied choice to the scientific activities of the medical man.

The Relation of the Medical Profession to the Housing Question.—Dr. S. A. Knopf of New York City divided the subject of this paper into a consideration of the selection of proper ground for dwellings with a view of assuring proper drainage, proper ventilation, plumbing, the necessary cubic air space for each individual, light, sunshine, and heating facilities. The paper further discussed the general sanitary arrangements of rooms, internal equipment, hygienic measures, and precautions to avoid what is commonly known as indoor diseases, dwelling upon the precautions which should be taken in dwellings to diminish the existence of dust and its danger as a disease carrier. Even the so-called sterile or non-pathogenic dust the author said could be productive of disease and he considered it the duty of the physician, hygienist, and sociologist to ascertain what could be done to reduce the fearful morbidity and mortality caused by indoor and dust diseases and infirmities brought about by the unhygienic housing of the masses in general. To hope for any appreciable results the cooperation of statesmen, public educators, and philanthropists was considered an absolute necessity.

General Aspects of the Housing Question.—Dr. Gertrude U. Light of New York City prefaced her paper upon this subject by remarking that the making of Americans, with the marketing of alien labor and the housing of the alien's family, have furnished much of the social history of the generation to the communities affected. Intelligence has reluctantly admitted, however, that mere reception is not humanizing; that the sentiment of liberty must be worked in terms of sanity, if decency is to distinguish the naturalized product. The housing problem, therefore, has, certainly in the cities, resolved itself into the immigrant's problem. Treatment must proceed along parallel lines. First, the regulation, in respect to members and fitness of the arriving alien; second, such personal and legislative activity as shall procure the construction and maintenance of model dwellings, and present the wasteful repetition on the outskirts of the processes which have created the central slums.

Mr. Paul Kennaday of New York City said that just so long as the public generally would tolerate the dreadful conditions of the tenement house dwellers so long would they exist. Although the foreigner was a part of the general public, he had not the ability to express his need, and it was the duty of the educated citizen to study and remedy the evil. Prisons generally were spoken of as hotbeds of tuberculosis, but reference was made to the prison in New York to which prisoners with tuberculosis were now sent with the result of reducing the mortality. The necessity was emphasized of placing questions of this kind before the public through the public newspaper rather than through medical journals. In the tuberculosis movement about 1,500 copies of a press pamphlet had been sent each week to a large number of newspapers in New York City. The same could be done in regard to the tenement house problem.

Mr. John Martin, Corresponding Delegate to the Women's Trade Union League, considered the housing problem almost entirely a city problem, the problem in the village being rather one of information concerning the construction of the house. The crucial point in the difficulty was to prevent the crowding in of so many people on a stated area. The most elaborate sanitary devices and housing methods could not cope with an increase of 80,000 in population in the last five years, as there had been in the restricted area of the lower part of Manhattan. The solution he thought, lay in making the cities bigger. Following the suggestion of Mr. Devine, this could be done in part by forbidding the erection of factories upon areas already full. While this would take the crowds away from the city centers the question of transportation would arise. To meet this difficulty he suggested for scientific consideration, apart from political theories, whether it might not be wise, by taxation or other means, to take into the common exchequer a part of that unearned increment of land value and spend this upon freeing the transportation facilities in order that the people might be taken out of the hotbeds of disease and of crime and put upon the borders of the city.

Miss Claghorn of New York City thought that from some points of view the housing in small towns and villages was worse than in the cities. In the small towns the difficulty lay in improper sanitation; in the cities, in the covering of ground space and in the height of buildings. She suggested that there should be legislation regulating the height of buildings.

Dr. Woods Hutchinson of New York City thought the housing problem not one solely of the great cities or of the slums. The modern hotel and the Pullman car offered illustrations of glaring lack of facilities for ventilation. Another point was in reference to the prevalent dread by many of night air, which he regarded as absolutely nothing but a survival of the dread of the powers of darkness and of the prince of the power of the air who might swoop down upon them and carry off their souls to perdition if the wind blew upon them at night. Regarding the building of model tenement houses, he believed such could be erected to give the owners a fair return if only the greed of the landlord could be moderated, and he thought it not too much to say that the mass of the voters of the country would see that this moderation were brought about. He believed that a limit would be placed upon the possibility of individual aggregation of wealth and the taking of an unfair part of the earnings of the poor.

Dr. Edward Jackson of Denver agreed that the solution of the problem of overcrowding lay largely in taxation that should secure the best value of lands, and the maintenance of transportation that should allow men to spread out over the largest districts of the country and in the encouragement of large manufacturers to spread out over a larger part of the country. Railroad discrimination was largely responsible for the phenomenal growth of cities, and this point should claim the attention of citizens in the matter of politics. The restriction of buildings to a certain height should also be a matter of legislative concern in order that natural light might be preserved for city dwellers.

Dr. H. O. Marcy of Boston spoke of the splendid transportation facilities in his city. Notwithstanding this, immigrants from Southern Russia or Italy naturally wanted to remain in the colonies of their fellow men.

Dr. Thomas D. Davis of Pittsburg said that in his city they had taken the factories out of town with the result that trains were run to carry the people back to the crowded districts. Although nice houses were near the works the people would not occupy them, desiring rather to get back to the life of the city.

Dr. Charles McIntire said that Dr. Spalding, who had been obliged to leave, had asked him to say that in Portland they had very little of the housing problem because the prohibition law was lived up to, and with the removal of temptation men had more money and there was no slum district.

What Is the Primary Cause of Non-Legislation and Mal-Legislation with Regard to Medical Matters?—Dr. Thomas H. Shastid of Marion, Ill., claimed that there was much amiss in the way of legislation in this country with regard to matters medical. A central operative condition accounting for this was said to reside in the ridiculous character of the instruction (or the total absence of instruction) given to-day in the courses on legal medicine and allied topics in the vast majority of our schools of law. The extent and character of medical instruction as it ought to be imparted in the law schools was described. It was asserted that the extra time and effort required of the law

student to acquire a proper knowledge of medical matters would in the end be to him no burden, but rather a benefit.

The State Board of Medical Examiners.—Dr. Henry Beates, Jr., of Philadelphia, presented some suggestions relative to improvements in the legislative regulation of medical licensure.

The Necessity for Cooperation in the Movement for a National Department of Health.—Professor J. Pease Norton of New Haven said that the success of the movement for a Federal Organization of Public Health work required widespread cooperation among all learned, philanthropic, and fraternal associations. The appointment of a Committee of One Hundred was the result of a vote passed by the American Association for the Advancement of Science at its Ithaca meeting, June 30, 1906. Since that date Professor Irving Fisher, Chairman, had appointed such a committee, consisting of persons identified with the leading learned and philanthropic societies which held these objects at least in whole or in part. The purpose of this committee or council was to secure cooperation among many great associations capable of wielding vast influence and representing the power requisite for accomplishing the definite objects proposed. To work out the problem special committees had been appointed on legislation, finance, publicity, organization of health clubs, and cooperation. Beyond the work of these committees a far larger problem was the practical one of adequately presenting the movement. It was thought that $100,000,000 appropriated annually by the Federal Government would not be large for 80,000,000 population. To accomplish the thorough rousing of the people to the necessities of the movement, it was stated that no more effective means could be imagined than the endowment of a great International Institute of Health at the Hague. International conferences should be held. Great laboratories should be endowed and equipped for experts devising inventions and discoveries against disease and death.

Criminal Abortion.—Dr. Henry W. Cattell of Philadelphia regarded the criminal abortionist as one of the greatest menaces to civilized society. That he existed in numbers, both within and without the medical profession, could not be denied. He thought it important that the public should be educated as to the wide extent to which the practice was now in vogue in order that popular sentiment might be made to condemn its performance. He gave a summary of the work done by the special committee of the Philadelphia County Medical Society to aid the officials in bringing this class of criminals to the bar of justice. The formation of the Public Health Defense League and the Pennsylvania Health Defense Association was described. The medicolegal aspects of abortion, especially with regard to state and national legislation, was discussed and a plea made for revoking the license of any registered physician found guilty of performing criminal abortion.

General George M. Sternberg opened the discussion upon the foregoing papers, speaking more especially upon the subject of Professor Norton's paper. While not wishing to throw cold water upon the project of a National Department of Health, he pointed out some of the obstacles which might be expected.

Dr. S. A. Knopf, in regard to examination for permission to practise medicine in another State, thought it preposterous to expect that every physician after he has been in practice for ten or fifteen years upon going to another State must submit to certain examinations in chemistry, physiology, and anatomy. He, therefore, believed that an established bureau of health should make a standard for permission to practise throughout the United States.

Dr. Ernest B. Hoag of Pasadena, Cal., said the examination questions usually propounded he thought did not tend to ascertain the final result of a man's education, but what he remembered of the things that he ought to forget.

Dr. John B. Roberts thought that because a man had practised medicine ten or fifteen years ago he was not necessarily competent to practise at the present time; and he contended that any man with a good medical education who had been licensed to practise, who could not within six or eights weeks refresh his memory sufficiently to answer questions of the average examining board, had no business to try to practise medicine.

Dr. Edward Jackson of Denver asserted that in the Colorado State Board rules of the preliminary examination were drawn up, but the examiners were not tied down to a particular form of examination.

Dr. M. G. Motter of Washington, D. C., said that from the fact that every one before examinations balked at anatomy, chemistry, and physiology, it was evident that these three studies were not properly taught in medical schools.

Dr. Henry D. Holton of Brattleboro, Vt., felt that examiners should aim to ascertain the practical knowledge that a man had and thought the point was well illustrated in the incident of the surgeon with private practice taking an examination for army service. Asked what tissues he would cut through in operating upon indirect inguinal hernia, he replied that he would cut through the skin and superficial fascia. He hesitated, then repeated what he had said, again hesitated, grew a little more excited, and finally said, "and after that I would cut pretty damned careful." Dr. Holton told briefly his method of dealing with the question of abortion. To his Protestant patients he presented a convincing little book telling why abortion should not be done. His Catholic patients he always advised to consult the priest.

Dr. Ruth Webster Lathrop remarked upon the high percentage of students and applicants for license to practise who failed in physiology, and as a teacher he asked for cooperation in helping the students.

Dr. Gardner T. Swarts questioned whether a National Examining Board would be satisfactory to any number of States.

Dr. Leartus Connor claimed that before there could be any effective regulation of the practice of medicine the people must be educated regarding conditions that should prevail.

Dr. Edwin B. Harvey said that the crime of abortion was not a medical question; that he who committed abortion was not practising medicine, but committing a crime against the statute of every commonwealth in the country.

Dr. Shastid in closing said that a National Examining Board was a practical impossibility, the Federal Government having no power to appoint an examining board. This power could be given to the government by the individual States by amendment to the constitution, brought about by a two-thirds vote of the States. This, however, was practically an impossibility.

Dr. Beates in closing asked the influence of the Academy in the passage of a medical law acceptable to all commonwealths and in the education of the public on matters medical.

Dr. Winfield S. Hall of Chicago made a brief plea for rational examinations, not only before State Boards, but before hospital boards and in the departments of medical schools to advance students from one year's work to another. The whole subject of examinations, he thought, had been on a wrong basis and that the effort should be rather to ascertain the real knowledge of the one examined than a matter of memory of textbook instruction.

Dr. Cattell, in closing, congratulated Dr. Holton upon his novel method of preventing abortion, and hoped to give wide publicity to that which should be known as "Holton's Method of Preventing Abortion." Regarding

the Pennsylvania law on abortion, in the work undertaken in this connection the committee had been assured that no medical law should pass the legislature that did not provide for the revocation of license in the event of the performance of criminal abortion. This promise had been kept so well that the Osteopathic Bill which had recently been passed by the Senate had attached to it the provision for the revocation of license for the performance of criminal abortion.

The Medical Superstition of the Precious Stones.—Dr. ROLAND G. CURTIN of Philadelphia read this paper.

Officers.—The following officers were elected: *President*, Dr. Thomas D. Davis, Pittsburg; *Vice-presidents*, Drs. James H. McBride, Pasadena, Cal.; Frederick T. Rogers, Providence, R. I.; Louis S. McMurtrie, Louisville, Ky.; *Secretary and Treasurer*, Dr. Charles McIntire, Easton, Pa.; *Assistant Secretary*, Dr. Alex R. Craig, Philadelphia.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, May 27, 1907.

WALTER LESTER CARR, M.D., PRESIDENT, IN THE CHAIR.

Memorial Address: George B. Fowler, M.D.—Dr. FRANK VAN FLEET reviewed, in this address, the life of Dr. Fowler, dwelling particularly upon his professional career in this city.

Presentation of Apparatus for the Continuous Administration of Nitrous Oxide Gas and Oxygen.—Dr. JAMES TAYLOE GWATHMEY presented this apparatus, explaining that the method is not applicable to all cases. Middle-aged persons and those who are weak and worn out from any cause were best suited for the continuous administration of nitrous oxide gas and oxygen, while the cases to be avoided were able-bodied men, athletes, and alcoholics. Dr. Gwathmey advocated giving morphine or atropine one-half hour before giving the anesthetic. According to this method the administration of the anesthetic could be prolonged sufficiently for the performance of any radical operation. He had given it continuously for two hours and the patient had gotten up from the table with no nausea and no vomiting.

Dr. JAMES IVES EDGERTON cited a case in which he had removed a fibroid tumor weighing thirty-six pounds from a colored woman whose condition was such that ether could not be administered. The operation was done under the combined nitrous oxide and oxygen anesthesia, administered by Dr. Gwathmey, the patient being in the reversed Trendelenburg position. The abdominal muscles were perfectly relaxed and though the anesthetic was given for two hours the patient had no subsequent vomiting or other disturbance.

The Differential Diagnosis of Imbecility and Dementia Precox.—Dr. A. R. DIEFENDORF of Middletown, Conn., read this paper. The differential diagnosis of imbecility and dementia precox could be summed up in a few words if the discussion be limited to the more exact definition of imbecility, *i.e.* lighter grades of arrested mental development, acquired or congenital. The question might be asked of such an originally defective individual who has reached the age of predilection for dementia precox, and of the development of whose symptoms no reliable history is obtainable, whether the patient be suffering from dementia precox and is now in a state of deterioration, whether his mental condition will become progressively worse, or whether he will remain permanently in his present condition. The question was one not easily answered, because terminal states of deterioration of dementia precox might not be unlike the original defects of imbecility. The difficulty was particularly apparent in the cases of insidiously developing dementia precox, which at no time presented hallucinations or delusions, but which exhibited a simple progressive deterioration of the mental life. Dr. Diefendorf cited a case of this type of dementia precox. In such cases the differentiation depended chiefly upon the fact that in dementia precox the patient had acquired and retained school knowledge, while the imbecile had been able to acquire such knowledge to only a moderate degree. Furthermore, the imbecile might be incoordinate in his movements, but natural movements were not peculiarly modified, as was the case with dementia precox patient. The differential diagnosis was rendered more complicated by the fact that from seven to nine per cent. of all cases of dementia precox develop on an imbecile basis, so that it was difficult to determine where imbecility ends and dementia precox begins. The difficulty was still further complicated by the fact that imbeciles not infrequently present brief exacerbations, the symptoms of which are quite like those of dementia precox. The differentiation here depended upon two factors, viz., first, that with the imbecile the active crazy symptoms are of comparatively brief duration (rarely over a few days or weeks), and second, that emotional deterioration, the characteristic symptom of dementia precox, is lacking, the exacerbation leaving the imbecile patient no worse than before. When the term imbecility was used in a broader sense and included certain of the constitutional psychopathic states, and of the psychopathic personalities, there were several groups of cases which might appear like cases of dementia precox, as for example, cases of constitutional despondency, constitutional excitement, and the so-called unstable personalities. The differentiation of these states from cases of dementia precox rested chiefly upon the absence of deterioration in the former.

Remarks on the Medicolegal Aspect of Imbecility.—Dr. L. PIERCE CLARK, in presenting this subject, called attention to the fact that twenty-eight States have no adequate provision for the feeble-minded, and that of the 140,000 such individuals in the United States only 6,000 are cared for in the twenty-seven institutions for the feeble-minded in this country. The difference between medical and legal definitions added artificial difficulties to those inherent in all that pertained to insanity and to imbecility as well. The term imbecility in law included not only arrested development, as in idiocy, but dementia, or the breaking down of intellect by disease or old age. In law imbecility was to be distinguished from lunacy in that it was without delusions or lucid intervals. The legal test of imbecility consisted in the inability of the subject to transact the ordinary affairs of life, to understand their nature and effect, and to exercise will in relation to them. There was, however, no single test of imbecility, and every case had come in medicolegal matters to be judged upon its own merits, in which tests of memory, judgment, emotional balance, personal conduct, and morals played important parts, as in medicine proper. The medicolegal distinction between idiocy and imbecility was quite as arbitrary as in ordinary medicine. The two states merged one into the other. From the sociologic point of view, however, it might be said that the imbecile is a much more dangerous member of society than the idiot. The imbecile might be said to be antisocial, while the idiot was extrasocial. Once the condition of imbecility was established before the law, the status of the imbecile was clear. The imbecile or feeble-minded person could execute no contract or conveyance; he was, in fact, under the same legal restrictions as a minor. It was interesting to note that this did not pertain with reference to epileptics, the medicolegal aspect of ordinary epilepsy concerning itself only with the mental state during the time of the fit. There were many reasons why mental incompetence in epilepsy should have a broader foundation than the fit period. The impropriety of permitting imbeciles to vote upon public questions was often manifest, but such individuals could not be refused the franchise so long as their defection had

not been legally declared. The law required less mental power for the execution of a will than for the making of a contract, and considerable distinction was made between important and common affairs, large and small properties, relative to the disposing power in wills. The just position of the Civil Code regarding limited responsibility for testamentary capacity offered a valuable and potent argument for the recognition of conditions of limited responsibility in criminal action. Laws prohibiting marriage of imbeciles and epileptics were on the statute books, but legislation was not sufficient to prevent procreation by and of idiots, and the idea of the castration of male epileptics, imbeciles, and idiots had not advanced beyond academic discussion. The legal status of the moral imbecile was less definite and fixed. Such antisocial factors were found in insane asylums as cases of moral insanity, cases of dementia precox, and paranoid states; in institutions for the feeble-minded as cases of imbecility with moral perversion; in reform schools and prison as incorrigibles and habitual criminals; in vagabondage as petty thieves and tramps, and among the better classes of society in homes and sanatoria for borderland psychoses and drug addictions. Dr. Clark strongly advocated suitable protective measures for the defective individual and for society. Humane segregation and not punishment should be aimed at. The establishment of juvenile courts presaged a juster and saner outlook for feeble-minded children who suffer moral perversion and who, through the commission of criminal acts, come into contact with the law.

The School Training of Backward Children in the New York City Schools.—Dr. Charles E. Atwood read this paper, in which he outlined the work accomplished in the so-called ungraded classes of the New York City schools. Of the nearly two million defectives in the United States, over one hundred thousand were feeble-minded, in contradistinction to the idiot or insane. The percentage was greater than in England, France, or Germany, and greater in New York City than in any other city. Of the seven thousand children in New York who were suitable for the ungraded classes, nearly all were foreign born, or native born of foreign parentage. The careful training given these defectives in the ungraded classes, together with the removal of adenoids, correction of visual defects, etc., had improved conditions to a remarkable degree, but there remained much yet to be accomplished. Mental defectives should be sent to a neurologist, who should determine whether such individuals should be sent to institutions or allowed to continue in the ungraded classes. Dr. Atwood recommended the cooperation of the County Medical Society and the Academy of Medicine with the Board of Education in perfecting the training of mental defectives.

Dr. Smith Ely Jelliffe advocated a better classification of mental defectives. Schools for backward children, idiots, and imbeciles were working in the right direction, and when such schools were properly located, properly manned, and equipped a great deal could be accomplished for these unfortunate individuals. The side of the question particularly interesting to the psychiatrist was what should be done with the constitutional inferiors, the constitutional psychopaths, those on the wavering edge between responsibility and irresponsibility, between mental health and mental illness. This was also a subject of greatest moment to the penologist. It was a question for the psychiatrist rather than for the penologist. The fitting of the punishment to the crime should be done with more skill and with more reliance upon the teachings of psychiatry.

Miss Elizabeth E. Farrel, instructor of the ungraded classes of the public schools, expressed appreciation for the cooperation of the County Medical Society with the Board of Education in the work of training the defectives of the city schools. It was only by cooperation of the medical profession with the school authorities that such work could be carried on as it should be. She dwelt upon the fact that a child was placed in the ungraded class only after careful study by a competent teacher, who goes into the home of the suspected child, who learns something of the economic status of the family, something of the family history, and of the child's previous history. After the teacher had obtained this information by personal, friendly visits, the medical examiner was called into requisition, and the child was given a thorough physical examination according to the methods employed in clinics. Mental tests, also, such as are employed in clinics and private practice by neurologists, were applied. Furthermore, a child was never placed in an ungraded class until he had had a fair and square test in the regular grades. She did not agree with those who hold that training such children was merely brightening up those who will become criminals.

Dr. Maximilian P. E. Grossmann said that the physician approaches the subject from the purely pathological point of view, while the educator approaches it from the educational point of view. Both views were one-sided, and it was only through correlation of the two that the end could be accomplished. He emphasized the importance of the proper diagnosis and proper classification of these cases. Epileptic and feeble-minded children had no place in ungraded classes, but should be segregated. Every school should have connected with it an alienist and neurologist, who should cooperate with the teacher in the proper placing of the child.

Dr. Adolph Meyer said this subject had been brought to his mind in connection with the work done at the dispensary of Cornell University Medical Department, where it was the endeavor to meet some of the conditions described. In the dispensary, however, one was at a great disadvantage, in that the child must be examined rapidly, out of his environment, and such examination was apt to be inferior to the efforts of the common-sense teacher. The child must be examined by the physician in its environment. The greatest advantage that they had been able to bring to the child at this dispensary was, in the first place, the opportunity to see the parental management of the child, and in the second place, the removal of adenoids, correction of visual defects, etc. Another advantage lay in the decision as to whether the child should be recommended to a special school for feeble-minded. The best work of the physician, however, was to be done in the schools themselves and not in the dispensary, and consisted in encouraging the teacher and trying to train the parents. Better diagnosis would improve the work. Many cases of terminal dementia had their beginning in school. The actual beginning of the disorder could, as a rule, be demonstrated to be a habit disorganization—habits which were very small in the beginning, and which were considered practically irrelevant.

Anesthetizing.—Gwathmey says that whenever possible the patient should be anesthetized on the operating table. There is no good reason why all operating tables should not be supplied with wheels. The patient could then be wheeled from the anesthetizing to the operating room, thus avoiding the lifting and jolting, and with no intermission as regards the anesthetic. If the patient is anesthetized in the operating room, every one should refrain from conversation until the patient is well under; neither should the patient be touched by any one until ready for the operation. Also the patient's room should be darkened, and quiet observed, after the operation. When the gas-ether sequence is used, surgeon, assistants, and nurses should be ready before the anesthetic is started. Surgical anesthesia is usually reached in three or four minutes, and the operation should begin at that time.—*Illinois Medical Bulletin.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

West Virginia State Board of Health.

November 13, 1906.

BACTERIOLOGY AND HISTOLOGY.

1. Mention three diseases of microorganismal origin and describe the organism of each.
2. Give three pus-producing organisms.
3. Which of the above in questions 1 and 2 is most widely distributed? Which is the most virulent, and why?
4. Through what channels do the organisms of tuberculosis, tetanus, anthrax, diphtheria, and typhoid fever enter the body?
5. What becomes of pathogenic bacteria in a dead body?
6. Where in the body is adipose tissue never found normally?
7. Name structural elements of nerve tissue.
8. Of what is a tooth composed?
9. What is a Peyer's patch?
10. What is periosteum, and how many layers?

HYGIENE.

1. What hygienic guards would you throw around a bottle-fed infant?
2. Why were the disabilities and deaths from disease so much less in the Japanese armies than in the American in the recent wars?
3. How would you prevent ophthalmia neonatorum?
4. What influence has the purity of water upon its power of dissolving lead?
5. Name five of the best disinfectants and explain their action and method of use.
6. Tell how you would prevent the spread of the following: Typhoid fever, diphtheria, scarlet fever, and smallpox.
7. What instructions would you give in a case of tuberculosis to prevent other members of the family from contracting the disease?
8. Describe your ideal for a sleeping-room from a sanitary standpoint.
9. What instructions would you give as to the toilet of mother and child in the first week after confinement?
10. Name some of the diseases whose germs are carried by water, and those carried by air. How may they be destroyed?

PRACTICE OF MEDICINE.

1. Practice of medicine. Define it. Is the use of patent medicines legitimate?
2. Differentiate between true croup and laryngismus stridulus; treat the latter.
3. Name four of the eruptive diseases and give period of incubation of each.
4. Hiccough: causes, symptoms, and treatment.
5. Differentiate between diabetes mellitus and diabetes insipidus; give urinary analysis of the former and some of the things found in it.
6. Differentiate between cancer and ulcer of the stomach.
7. Describe the clinical thermometer; give three methods of using it and variations.
8. Scabies: describe and treat.
9. Biliousness: give causes, symptoms, and treatment.
10. Warts and corns: describe and treat—nonsurgical.

PHYSIOLOGY.

1. Describe lymphatic circulation. What does it do and how does it do it?
2. Give function and description of various blood corpuscles. What regulates blood pressure and how measure it?
3. How does bone grow? Purpose of Haversian canals? Function of marrow and periosteum?
4. Describe development, construction, and use of teeth. What glands are affected by mastication?
5. What is function of the vagus nerve?
6. Locate and give function of thymus, thyroid, and suprarenal glands.
7. Describe the portal circulation.
8. Describe prostate gland and detail its functions. How does ovum get to uterus?
9. Detail minute anatomy of skin and function of each part.
10. Describe the process and purpose of respiration. Why an involuntary act?

ANATOMY.

1. Locate and describe the ileocecal valves.
2. With what bones does the malar articulate?
3. What muscles form the tendo Achillis, and where is the tendon inserted?
4. Name the branches of the abdominal aorta.
5. How is the eye supplied with blood?
6. What constitutes the brachial plexus?
7. How are the saphenous veins formed, and where do they empty?
8. Give the anatomy of the bladder.
9. Describe the ankle joint.
10. Name the arteries and veins passing to and from the kidneys.

CHEMISTRY.

1. What is a molecule?
2. Define an acid, a base, a salt.
3. What is the most common element in nature?
4. What is uric acid? Tell all you know about it.
5. Name five acids used in medicine, and give their formulæ.
6. Name five preparations of mercury used in medicine.
7. Define distillation and sublimation and give examples.
8. What is the therapeutic value of alcohol?
9. Give color, reaction, and weight of normal urine.
10. Give a reliable test for albumin, bile, blood, and sugar in the urine.

OBSTETRICS AND GYNECOLOGY.

1. Give the diameters of the true pelvis.
2. What is the perineum? How should it be protected?
3. How is the semen carried to the ovum?
4. Give various changes which take place in ovum after impregnation.
5. Name the different presentations of the fetus at the end of gestation. Which are normal, which abnormal?
6. What are the indications for instrumental delivery? Would you call help?
7. How long would you remain with patient after delivery? What symptoms would cause you to delay your going?
8. Give symptoms, diagnosis, and treatment for chronic endometritis.
9. Give symptoms, diagnosis, and treatment of a small fibroid of uterus growing from margin of internal os extending upward in wall of uterus.
10. Diagnose and treat a case of placenta previa—central, marginal.

SURGERY.

1. What is hemorrhage? Divide anatomically and clinically; treat mechanically and therapeutically.
2. Describe, differentiate, and treat furuncle and carbuncle.
3. Describe, give symptomatology, and treatment of dislocation of inferior maxillary bone.
4. Exarticulate humerus, give steps, and tell all you know.
5. Trephining, give indications, precautions, and complications.
6. Define gonorrheal urethritis, give complications, sequelæ, and treatment.
7. Mention the dangers of anesthesia, and treat case of chloroform, ether, and cocaine poisoning.
8. Give form of historical examination.
9. Differentiate piles, fistula, and fissure; treat each.
10. Differentiate phimosis, paraphimosis; treatment.

MATERIA MEDICA, AND THERAPEUTICS.

1. What per cent. are the two classes of tinctures in the new pharmacopœia?
2. Give the official preparations of mercury, and the diseases in which its use is most indicated.
3. Name the three best teniacides and the dose of each.
4. What is meant by coaltar derivatives, and what is their action in general?

*It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any textbook on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the candidate with the general character of these examinations and to inspire him with confidence in the result of his trial.

5. Mention the ingredients of citrine ointment; what is its official name?

6. State the effects of the bromides on the respiration and on the action of the heart; what effect is the long-continued use of the bromides liable to produce on the mental functions?

7. Write a prescription for a four-ounce mixture containing an expectorant, a sedative, and a tonic of which the dose is a teaspoonful every two or three hours.

8. Give the composition of the compound cathartic pill; state the dose.

9. Define hemostatics; their mode of action, the best local hemostatic; therapeutics.

10. What are counterirritants? Explain their action and the rationale of their use in diseases; enumerate four in the order of efficiency.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

WEST VIRGINIA STATE BOARD OF HEALTH.

November 13, 1906.

BACTERIOLOGY AND HISTOLOGY.

1. (1) Typhoid fever, caused by the *Bacillus typhosus* of Eberth; (2) tuberculosis, caused by the *Bacillus tuberculosis* of Koch; (3) diphtheria, caused by the *Bacillus diphtheriæ* (Klebs-Loeffler bacillus).

2. (1) *Staphylococcus pyogenes albus;* (2) *Staphylococcus pyogenes aureus;* (3) *Streptococcus pyogenes.*

3. The *Staphylococcus pyogenes aureus* is the most widely distributed; the *Streptococcus pyogenes* is the most virulent, because it is the most active in the production of soluble toxins.

4.

ORGANISMS OF:	ENTER THE BODY BY THE FOLLOWING CHANNELS:
Tuberculosis	Respiratory tract, alimentary tract, skin, and mucous membranes.
Tetanus	Wounds of skin and mucous membranes.
Anthrax	Wounds of skin and mucous membranes, mouth, and respiratory tract.
Diphtheria	Mouth, nose; wounds.
Typhoid fever	Mouth.

5. Most of them die; some, because they can hardly exist at any other than the temperature of the living body; others, because they cannot obtain suitable nutriment from dead tissues. Others, again, are rapidly killed by other organisms with which they come in contact and against whom they are powerless to compete. Some may eventually enter another host.

6. Adipose tissue is never found normally in the penis, scrotum, eyelids, nymphæ, cranial cavity, and the lungs (except near the root).

7. The structural elements of nerve tissue are:—(1) The nerve cells (consisting of protoplasm, nucleus, nucleolus, axis cylinder process, and dendrites); (2) the nerve fibers, (*a*) *medullated,* consisting of axis cylinder, medullary substance, and neurilemma or sheath of Schwann; (*b*) *non-medullated;* (3) the supporting tissues and neuroglia.

8. A tooth is composed of dentine, enamel, cementum, and pulp.

9. Peyer's patches are oval groups of lymph follicles, packed closely together, and held in place by diffuse adenoid tissue; they are situated chiefly in the ileum, and are found in the mucous and submucous layers.

10. Periosteum is a tough fibrous membrane surrounding a bone. It consists of two layers.

HYGIENE.

2. Because:—The Japanese expected war and were prepared for it; they knew that disease was more fatal than bullets, and had their medical department thoroughly well prepared and organized and under the absolute control of well equipped medical officers; the soldiers had suitable rations, which were purchased, inspected, and transported without political or civil interference; all the medical (and military) appointments were made on the basis of skill and experience, and whatever the health and sanitary condition of the soldiers required was promptly provided, without being dependent on the vanity, ignorance, or political aspirations of the military officers; in a word, politics was absent.

3. Ophthalmia neonatorum can be prevented by:—(1) Taking the utmost precaution to prevent sepsis during and after labor, and (2) instilling into the eyes of every newborn infant one drop of a one or two per cent. solution of nitrate of silver.

4. As a rule, the purer the water the more liable it is to dissolve lead.

10. Diseases whose germs are carried *by water*:—Typhoid, cholera, dysentery; sometimes also diphtheria. The germs may be destroyed by boiling the water used either for drinking or for washing vessels, etc., used in connection with food or cooking.

Diseases whose germs are carried *by air*:—Tuberculosis, scarlet fever, smallpox, measles, pneumonia, influenza, diphtheria, and erysipelas.

The germs may be destroyed by the proper use of antiseptic solutions.

PRACTICE OF MEDICINE.

1. *Practice of medicine* may be defined as all that appertains to the knowledge, prevention, and cure of disease.

The use of patent medicines is legitimate.

2. *True croup* is either laryngeal diphtheria or a streptococcus infection. In either case there is a prior stage of malaise, accompanied by chills, fever, and sore throat. The fever may become high. A membrane forms, in which are found the Klebs-Loeffler bacillus or streptococci. The child is hoarse, suffers from dyspnea, and may expectorate shreds of false membrane; there is prominence of the suprasternal notch and of the sternomastoid muscles.

In *laryngismus stridulus* the child holds his breath, the face becomes congested and cyanotic, the glottis is closed, inspiration is suddenly arrested, and ends in a shrill crowing sound; there may be spasms or convulsions; the attack is sudden, and may be repeated; there is no fever, coryza, nor cough.

Treatment of laryngismus stridulus:—Cold water should be dashed on the face and chest; ammonia may be applied to the nostrils; an emetic may be administered, bromides or chloral should be given; attention must be paid to the diet and general hygiene of the child.

3. Typhoid fever, incubation period two to three weeks; measles, ten to fourteen days; scarlet fever, one to ten days; erysipelas, one to five days.

4. *The cause of hiccough is*:—Sudden clonic spasm of the diaphragm, with closure of the glottis. This may be due to:—(1) Irritation of the stomach or lower end of esophagus by food, or indigestion; (2) irritation of the phrenic nerve by pressure of a tumor or aneurysm; (3) hysteria or various neuroses; (4) diseases of the gastro-intestinal tract; (5) various constitutional diseases.

Symptoms:—Hiccough is itself a symptom.

Treatment:—Cold drinks, ice, brandy, pressure or cold on the epigastrium, emetics, the induction of sneezing, inhalations of chloroform or nitrite of amyl, hypodermic injection of morphine, pressure or galvanism over the phrenic nerve have all been tried with and without success.

5. *In diabetes mellitus* the urine has a high specific gravity and contains glucose; complications are many and frequent.

In *diabetes insipidus* the urine has a low specific gravity and does not contain glucose; complications are rare.

Urinary analysis of diabetes mellitus shows:—Great increase in the amount voided, high specific gravity, pale color, sweetish or aromatic odor, sweetish taste, increase in the amount of urea. Glucose is present; acetone, diacetic acid, and beta oxybutyric acid may be present.

6. *Cancer of stomach* does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs sometime after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; there is progressive emaciation; severe anemia and cachexia are also present.

Ulcer of stomach is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

7. Three methods of using the clinical thermometer:—(1) In the *mouth*: The thermometer should be placed under the tongue and to one side, and the patient should keep his lips closed. It should be kept in the mouth for about three minutes, and the patient should not have taken a very hot or a very cold drink for some time before the taking of the temperature. (2) In the *axilla*: The axilla should be dry, and the bulb of the thermometer be placed in the hollow; the elbow should be placed against the thorax, and the forearm brought across the chest. No clothing should be in the axilla or in contact with the thermometer. Five minutes is required to take the tempera-

ture. (3) In the *rectum*. The rectum must be empty; the thermometer is oiled and inserted two inches; it should remain in five minutes.

The temperature will vary according to the place where it is taken. Thus, if the temperature is 98.6° F. in the mouth, it will be about 98.2° F. in the axilla or groin; about 100.2° F. in the rectum, and a little higher in the vagina.

8. "Scabies is a contagious, animal, paracitic disease due to the *Sarcoptes scabiei*, characterized by burrows and a multiform eruption, and attended by severe itching. The eruption usually occupies certain areas where the skin is thin; these are the interdigital spaces, the flexor surface of the wrist and arm, the anterior and posterior axillary folds, the mammæ and nipples (in women), the umbilicus, the buttocks, the penis, the inner side of the thighs and legs, and the toes. The face is exempt except occasionally in infants. The itching is intense and worse at night. The affection is curable, but dermatitis may result from over-treatment.

"*The treatment* consists in a protracted bath with soap and hot water, followed by the application of sulphur ointment (℥ 1 to ℥1) or other parasiticide every night for one week. In the meantime, the bed linen and underclothing should be sterilized by heat. At the end of a week another bath should be taken and some sedative ointment or lotion should be prescribed. Sulphur may be substituted by beta-naphthol, balsam of Peru, styrax, tar, staphisagria, etc." (Gould's and Pyle's *Cyclopedia of Medicine and Surgery.*)

PHYSIOLOGY.

1. The lymphatic circulation is, strictly speaking, not a circulation at all; since the lymph flows only in one direction, namely, toward the heart. The lymph capillaries take up any excess of the blood plasma which is not required for the nutrition of the tissues. These capillaries consist of a single layer of epithelium, and empty themselves into vessels very like the veins. The lymph vessels are well provided with valves, which are so closely approximated as to give the vessels a beaded appearance. All the lymphatic vessels, except those of the right upper half of the body, empty into the thoracic duct, which terminates in the left subclavian vein, where the left internal jugular vein also enters. Those from the right upper half of the body discharge into the right lymphatic duct, which, in turn, empties into the right subclavian vein at its junction with the right internal jugular vein.

The forces concerned in the circulation of the lymph are: (1) The pressure of the blood in the blood-vessels; (2) thoracic aspiration; (3) muscular contractions of the voluntary muscles; (4) contractions of the intestine; (5) the action of the valves in the lacteals and lymphatics.

2. The *red corpuscles* supply the tissues with hemoglobin; the *white corpuscles* serve as a protection to the body from the incursions of pathogenic microorganisms, they take some part in the process of the coagulation of the blood, they aid in the absorption of fats and peptones from the intestine, and they help to maintain the proper proteid content of the blood plasma.

The *red corpuscles* are biconcave discs, about 1/3200 of an inch in diameter; they are non-nucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They contain hemoglobin.

The *white corpuscles* are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named.

There are also *platelets*, which are very small, colorless, irregular shaped bodies; they are about one-fourth the diameter of a red corpuscle. Their function is not determined; it is possible that they take some part in the coagulation of the blood. In number they vary from about 200,000 to more than 500,000 in each cubic millimeter of blood.

Blood pressure is *regulated* by:—(1) The force and frequency of the ventricular systole, (2) the quantity of blood contained in the vessels, (3) the elasticity of the walls of the arteries, and (4) the resistance in the capillaries.

Blood pressure is *measured* by the aid of a manometer or U-shaped tube containing mercury, one limb of which is attached to a lateral branch of the blood-vessel in which the blood pressure is to be measured. This attachment is made by means of a non elastic tube and canula filled with a watery solution of sodium carbonate or magnesium sulphate. The blood, through this solution, forces the mercury up in the distal tube of the manometer. The blood pressure is the difference in the height of the mercury in the two limbs of the manometer.

3. Bones grow *in length* at the two ends of the shaft; this is due to the process of ossification in the cartilage situated between the epiphysis and diaphysis. Bones grow *in thickness* by the development of successive layers beneath the periosteum.

The *Haversian canals* contain the blood-vessels, lymphatics, and nerves of the bone.

The *function of marrow* is:—The formation of the red blood corpuscles.

The *function of periosteum* is:—(1) The nutrition of the bone, (2) the growth of bone, and (3) the regeneration of bone.

4. The glands affected by mastication are:—The salivary glands (parotid, submaxillary, and sublingual) and the gastric glands.

5. *Functions of the vagus*:—"Throughout its whole course the vagus contains both sensory and motor fibers. To summarize the many functions of this nerve . . . . it may be said that it supplies (1) *motor* influence to the pharynx and esophagus, stomach and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part, (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc." (Kirkes' *Physiology.*)

6. *The thymus gland* is found only in infancy and childhood; it is *situated* in the lower part of the neck and in the anterior mediastinum, behind the sternum, and resting upon the pericardium.

The *function of the thymus* is not settled; it is said:—(1) to be a blood forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity.

The thyroid gland is situated on the anterior and lateral surfaces of the upper part of the trachea.

The *function of the thyroid* is not definitely settled; (1) it has some trophic function; (2) it is supposed to antagonize toxic substances; (3) it produces an internal secretion.

The suprarenal glands are situated in the back part of the abdominal cavity, behind the peritoneum, and above and slightly to the front of the upper part of each kidney.

The *function of the suprarenals* is not definitely settled; they produce an internal secretion which is probably necessary to life; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body.

8. The *functions of the prostate gland* are:—(1) The secretion of the prostatic fluid; (2) to act as an involuntary sphincter to the bladder; (3) its muscular fibers are also involved in the contraction that expels the semen during ejaculation.

The following theories have been held to account for the conveyance of the ovum to the tubes and uterus:—(1) That the fimbriated extremity of the tube becomes erectile and, aided by muscular contraction, grasps the ovary; (2) that the ova are ejaculated from the follicle into the tube; (3) that the ova are carried along in the serum by currents generated by the ciliated epithelium which covers the fimbriæ of the tubes; (4) in a certain number of cases there is a migration of ova, which pass across the abdominal cavity and come down the opposite tube. (From Edgar's *Obstetrics.*)

CHEMISTRY.

1. A molecule is the smallest quantity of a substance (either element or compound) that can exist in a free state.

2. An *acid* is a compound of an electro-negative element or radical with hydrogen, part or all of which hydrogen it can part with in exchange for an electro-positive element, without the formation of a base.

A *base* is a ternary compound capable of entering into double decomposition with an acid to produce a salt and water.

A *salt* is a substance formed by the substitution of an electro-positive element for part or all of the replaceable hydrogen of an acid.

3. Oxygen.

4. Uric acid, also known as lithic acid, is a dibasic acid, and has the formula $C_5H_4N_4O_3$. It occurs in the urine, and in smaller amounts in the blood and tissues. It is not found free, but as sodium urate; it is derived from the purin bases of the nucleoproteids. About 6 to 9 grains are voided in the urine daily. Pure uric acid is odorless, tasteless, and very slightly soluble in water; it crystallizes in small colorless rectangular or hexagonal plates or in

rectangular prisms; crystals from the urine are lozenge-shaped and are colored.

5. Sulphuric acid: H_2SO_4; nitric acid: HNO_3; hydrochloric acid: HCl; acetic acid: CH_3COOH; phosphoric acid: H_3PO_4.

6. Mercurous chloride; mercuric chloride; mercurous oxide; mercuric oxide; mercuric iodide.

7. *Distillation* is the conversion of a liquid into a gas, followed by the reconversion of the gas into a liquid. *Example*:—The distillation of water.

Sublimation is the conversion of a solid into a gas (without passing through the liquid state) and the reconversion of the gas into a solid. *Example*:—Sulphur can be sublimed by heating in a suitable apparatus.

8. "Though decidedly injurious in health, in disease alcohol is a most valuable remedy in appropriate cases. In *vomiting* of yellow fever, seasickness, etc., iced champagne is useful. *Atonic indigestion* of nervous and depressed subjects, cautiously. *Phthisis*, it does good if it promotes digestion and assimilation; otherwise it is very injurious. *Cholera infantum, diarrhea, etc.*, Cognac brandy in full doses. *Cardiac failure*, brandy in small doses repeated as fast as oxidized. *Chloroform anesthesia*, ℥ j-ij of whiskey beforehand, to sustain the heart, and prolong the chloroform narcosis. *Poisoning* by cardiac depressants and snake venom, alcohol freely, to sustain the heart. In snake poisoning it is given *ad libitum*. *Diphtheria*, whiskey or brandy in small doses frequently from the commencement, and dilute alcohol sprayed into the throat, is very efficient treatment. *Adynamic fevers*, small doses frequently are often of great value. *Gonorrhea*, Niemeyer is said to have done a lucrative business by treating this affection with injections of tannic acid in port wine. *Insomnia* from cerebral anemia may be prevented by small doses of some alcoholic stimulant at bedtime. *Wounds*, no better dressing than strong alcohol, to prevent putrefaction and protect the surface by coating it with a coagulum of its own albumen. *Bed sores* if threatening, alcohol locally, to harden the tissue. *Cold* from exposure, may be prevented by a moderate dose of alcohol, to restore the balance of the circulation and prevent internal congestion, by relaxing the vessels of the periphery." (Potter's *Materia Medica*.)

9. Normal urine varies in color from a very pale yellow to a brownish orange; the reaction is acid; the quantity voided in twenty-four hours is about fifty ounces.

10. Test for *Albumin*.—The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

Test for *Bile*.—Put 3 c.c. HNO_3 in a test tube, add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquids, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

Test for *Blood*.—To the urine add a solution of potassium hydroxide to distinct alkaline reaction; heat nearly to boiling (do not boil). A red precipitate is produced.

Test for *Sugar*.—Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color. (Witthaus' *Essentials of Chemistry*.)

OBSTETRICS AND GYNECOLOGY.

1. The pelvic diameters are easily remembered from the following table:

	Antero-posterior	Oblique	Transverse
Brim	4 inches	4½ inches.	5 inches.
Mid-plane	4½ "	4½ "	4½ "
Outlet	5 "	4½ "	4 "

3. Immediately after coitus, the cervix of the uterus is normally immersed in a pool of seminal fluid. Some of this passes up into the uterus, and it may or may not be assisted by the suction or aspiration power of the uterus. The spermatozoa travel by virtue of the vibratory motion of the tail or flagellum.

5. The different presentations are:—
   1. Head: including vertex, brow, and face.
   2. Breech: which may be breech, knee, or foot.
   3. Transverse: including shoulder, arm, and head.

Of these, the vertex (when the occiput is anterior) is the normal presentation; the others are abnormal.

6. *Indications for the use of forceps* are: 1. *Forces at fault*: Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2 *Passages at fault*: Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault*: A. Dystocia due to (*a*) occipito-posterior, (*b*) mento-anterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 4. *Accidental complications*: Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both. (From Jewett's *Practice of Obstetrics*.) I should certainly seek assistance.

7. The physician should remain with his patient, or at least be within call for an hour or more after the completion of labor. A pulse near or over 100, or inadequate uterine contractions, should cause the physician to delay his departure.

SURGERY.

1. *Hemorrhage* is loss of blood from some part of the arterio-venous system.

The *anatomical varieties* are:—Arterial, venous, and capillary.

The *clinical varieties* are:—Primary, intermediate or recurrent, and secondary.

Mechanical treatment includes:—Elevation, pressure, torsion, ligation, compression, acupressure, and forced flexion of limb.

Therapeutic treatment includes the use of:—Heat, cold, styptics, and the cautery. The constitutional symptoms must also be treated:—lower the head, inject normal salt solution, administer alcohol, strychnine, digitalis, morphine.

MATERIA MEDICA AND THERAPEUTICS.

1. In the new pharmacopœia the official tinctures vary in strength from 0.4 per cent. to 50 per cent. By far the greater number fall into two classes:—10 per cent. for the more powerful substances and 20 per cent. for the others.

2.

Official Preparations of Mercury	Chiefly Indicated in:
Ammoniated mercury	Ozœna psoriasis, tinea, and other skin affections.
Bichloride of mercury	Syphilis, anemia, summer diarrhea.
Calomel	Syphilis, biliousness, dropsy, dysentery.
Red oxide of mercury	Syphilitic sores, chronic skin diseases.
Yellow oxide of mercury	Indigestion, syphilitic sores, chronic skin diseases.
Red iodide of mercury	Syphilis, acute tonsilitis.
Yellow iodide of mercury	Chronic Bright's disease, syphilis.
Solution of mercuric nitrate	Epitheliomata, warts, lupus.
Ointment of mercuric nitrate	Chronic skin diseases.

3. Aspidium, dose of the oleoresin gr. xxx; granatum, dose of the fluid extract, ♏xxx; kousso, dose ℥iv.

4. Coal tar derivatives are substances derived from the aromatic or closed-chain series; they are synthetic products.

Their action in general may be said to be:—(1) Antipyretic; (2) stimulating to the nervous system, but later on causing paralysis; (3) antiseptic; (4) irritant and toxic to the cells and tissues of the body; (5) they also tend to produce methemoglobin and to disintegrate the red blood corpuscles.

5. The ingredients of citrine ointment are:—A hot solution of mercury, nitric acid, and lard. Its official name is *Unguentum Hydrargyri Nitratis*.

6. The bromides cause a slowing of the respiration, and a weakening of both the force and frequency of the heart. Their long-continued use causes an impairment of the mental functions, with melancholia or hallucinations, and sometimes a suicidal tendency.

7. ℞ Strychninæ sulphatis gr. ss.
   Codeinæ sulphatis gr. viij.
   Syrupi scillæ ℥jss.
   Glycerini ℥ss.
   Aquæ destillatæ q. s. ad ℥iv. Misce.
   Sig: Take one teaspoonful every three hours.

8. The compound cathartic pill consists of:—Calomel, about one grain; compound extract of colocynth, about one and a quarter grains; resin of jalap, about half a grain; and gamboge, about one-quarter of a grain. The dose is two pills.

9. Hemostatics are agents which, on being administered internally, arrest hemorrhage. Agents which act in this manner on being applied locally are called styptics. The former act by causing the vessels to contract; the latter sometimes in the same way and sometimes by promoting clot formation in the mouths of the wounded and bleeding vessels. Ergot, gallic acid, digitalis, hamamelis, and ipecac are hemostatics. As styptics may be named the actual cautery, acids, nitrate of silver, alum, collodion, and vegetable astringents.

10. Counterirritants are substances which, on being applied to the skin, produce more or less vascular excitement, and exert some beneficial reflex influence on a part remote from the site of application.

"The entire basis for the employment of counter irritation rests upon reflex action, or the conduction of a nervous impulse to a center, which, when so stimulated, sends out an impulse to the part of the body which is diseased.

"The use of counterirritation may be divided into four parts or purposes: The first is for affecting inflammations or congestions; the second for causing the absorption or removal of inflammatory deposits after true inflammation has ceased; while the third purpose is for the relief of pain; and the fouth for the effect which can be exercised upon the general system by blisters in systemic disease." (Hare's *Practical Therapeutics.*)

Four counterirritants:—Cantharides, capsicum, mustard, ammonia.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATS.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery.	Montgomery		
Arizona*	Ancil Martin, Phoenix	Phoenix	October	7
Arkansas*	F. T. Murphy, Brinkley	Little Rock	October	8
California*	Chas. L. Tisdale, 1870 Sutter Street, San Francisco	Los Angeles	Dec.	3
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	October	1

Missouri.—The new medical practice act passed by the last legislature became effective on June 15. Under the provisions of this act anyone desiring to practise medicine in this State must have a license from the State Board of Health, and none but graduates of reputable medical colleges may appear before the board for examination for a license to practise.

THE OPERATIVE TREATMENT OF FRACTURES INVOLVING THE ELBOW JOINT.*

BY CARLETON P. FLINT, M.D.,

NEW YORK.

ASSISTANT ATTENDING SURGEON TO THE ROOSEVELT HOSPITAL; INSTRUCTOR IN SURGERY AT THE COLLEGE OF PHYSICIANS AND SURGEONS OF COLUMBIA UNIVERSITY.

With development of the aseptic method of operation has gone hand in hand an increasing tendency to interfere by open operation in the treatment of fractures. Formerly it was bad enough to have the accident furnish the compound fracture, and such a thing as rendering a fracture compound for therapeutic reasons was carefully avoided except under unusual and extreme provocation. As the experience with compound fractures accumulated, it became apparent that the treatment as a whole was based on certain universally accepted principles, no matter what the detail variation might be in different medical centers of the world.

The favorable results with reference both to function and restitution of normal anatomical relationship naturally gave rise to attempts to improve the condition of patients who were afflicted with fracture effects impairing the use of the affected member. In due course of time it became an established custom to operate upon pseudoarthrosis and nonunited fractures. Clinical experience soon showed that certain simple fractures would better be operated practically at the time of injury. Except for a few bold pioneers, there was a tendency to avoid rendering compound any extremity fracture which involved a large joint.

After Blumhardt's bilateral arthrotomy in 1847 for vicious fracture of the elbow, the cases are scattered, and few, until with Lister's writing of the patella, in 1878, the start was given to the open method of treating fractures involving joints. At the present time every surgeon has had some experience, and particularly during the last five years there has been much interest shown throughout the surgical world, as evidenced by the numerous case records reported and monographs bearing on this subject. In spite of the success, one is forced by analysis of clinical experience to conclude that open operation is not always indicated, although there be considerable deformity and interference with function or the prospect of obtaining a fairly good result by conservative treatment seems slight.

In children particularly one must remember that a good acting joint and useful member results frequently after months of waiting, when at the time of injury it did not seem possible to preserve even a part of the normal arc of motion. When attacking old joint fractures one must also be able to decide that, all things considered, the chances are greatly in favor of improving the patient's condition.

*Read before the Surgical Section of the New York Academy of Medicine, February 1, 1907.

On the other hand, when interfering in fresh breaks, one is permitted to consider as a satisfactory result a useful member with motion over and above what is to be expected from nonoperative care. In old fractures, any improvement at all is success.

Before taking up more in detail the group which interests us in particular this evening, it may be well to call to mind some of the anatomical facts of surgical interest. We shall omit all description of the individual fractures as being elementary.

The anatomy of the child's joint is complicated by the existence of epiphyses in various stages of ossification, a knowledge of which, both with reference to shape, position, and progress of ossification, is essential.

Wilms has pointed out that the nucleus of the eminentia capitata appears at $2^1/_2$, the epitrochlea at 9, the trachlea at 10, the epicondyle at $10^1/_2$; and Wendt states that the shadows of the nuclei appear as follows: eminentia capitata at 1 year, the epitrochlea at 7-8 years, the trochlea at 10 years, the epicondyle at 12 years. The nucleus of the head of the radius at 7, the olecranon at 9. Oberst states that bone is formed in the olecranon at 12, and, according to Henle, a second or even a third nucleus appears later. At 15 the eminentia capitata trochlea and epicondyle form one piece. The nucleus of the epitrochlea is separate up to 19 years, and the trochlea separate from diaphysis up to 18 years. Wolff states that the rotula and trochlea are separate up to 13, and that the diaphysis unites with the epiphyses as a whole at 18.

We have examined 54 elbows, of which *x*-ray prints are at our disposal, and find that as far as the appearance of the shadow is concerned, no definite time applies to all cases. In a general way the data are as given above by Wilms and Wendt. There is, however, a margin of two to three years in all cases, both with reference to the time that the nucleus throws a shadow and to the time at which the various nuclei unite with each other and with the diaphysis. It is far more important to recognize a nucleus, when seen in the plate, and be able to state whether or not it is in its correct anatomical position. For this reason the study of the shape and relative position of the nuclei as shown by the *x*-ray plate is essential to the proper interpretation of shadows.

With the exception of the triceps, brachialis anticus, and anconeus, the muscles are of importance more as groups than as individuals.

It must be borne in mind that the synovial membrane reaches up about 1 inch above the coronoid fossa in front, whereas behind it stops at about the level of the top of the olecranon fossa, the difference in height being about 1 inch. On the inner side behind, the synovial membrane extends out close to the epitrochlea, whereas in front there is a free surface of bone about $^3/_4$ of an inch wide. Externally there is a narrow rim of synovial membrane in front and behind which is continuous below with the pouch about the head of the radius.

It is also important to remember that the median

nerve passes over the middle part of the trochlea and the radial nerve lies over the inner part of the capitulum. The ulna nerve in its groove is in close contact with and lies upon the capsule of the joint for a distance of about 1½ inches.

With regard to instruments, two things are essential beyond all others: the first a quickly acting drill, easily managed; the second, proper material for the fixation of fragments. Of drills, the electric drill, devised by Hartley and Kenyon, of this city, is, as far as I know, the best. Martin, of Philadelphia, has already emphasized that if wire is to be used, phosphor bronze is the best, being stronger and more pliable than silver. If silver is to be used it must be heated until red hot and then allowed to become cold before using. Specially constructed screws and bone or ivory pegs are also used, and for most work about the elbow strong No. 4 chromic gut, or the above-mentioned bone pegs, will be found sufficient to retain fragments in place after once reduction has been accomplished. Silk has also been used with success by Ajraghi, who reports a series of olecranon fractures treated in this manner.

Hartley uses several small aluminum wads inserted into the cortex as far as possible. Anderson of England has invented ingenious spikes and clamps. Lambotte, of France, has prepared a series of six forceps, serving various purposes, as well as special screws. Lane, of England, has also constructed various clamps and combination screwdriver and holder, which aid materially the manipulation of bone fragments. Another type of powerful forceps has been advocated by Rochet.

Lambotte lays stress upon the accurate establishment of anatomical relationship, and has termed the technique of the operative procedure osteosynthesis.

The first step is to expose the break; the second, temporary fixation in reduced position; the third, permanent fixation and closure of the wound. As Lambotte justly points out, and for which purpose his above-mentioned clamps were constructed, the temporary fixation should be accomplished before and maintained while the drillings and subsequent steps of permanent fixation are in progress. Any other procedure is inaccurate. In my experience it has not always been possible to fix before drilling.

The position of the patient, although largely a matter of personal choice, will nevertheless influence the ease of operating. It has been our custom to make anterior incisions with the arm abducted at a right angle and with the forearm supine. Posterior operations are to our way of thinking more easily accomplished with the arm flexed across the patient's chest, the forearm being prone.

Method of approach.—Just as the patella side of the knee is the route of election when operating on this joint, so the olecranon side of the elbow is the region of choice when interfering in the majority of fractures involving this articulation. Weber has aptly pointed out that the keystone to the elbow joint is the olecranon. The incisions applicable to the individual cases will be considered in connection with the types of fractures discussed.

Compound fractures will not be touched upon in this paper, inasmuch as they constitute a class of accident worthy of separate consideration by virtue of the varying indications, depending upon the character of each injury. All subsequent remarks refer to simple fractures.

The time of operation.—With the exception of a fracture which is complicated by injury to the brachial artery, no fracture about the elbow is immediately operable. It might be possible, perhaps, for a fragment to become so wedged in as to be practically immobile, and at the same time press upon the skin, threatening at any moment to render the injury compound. An epicondyle or internal condyle might do this, but if it does happen it certainly is a rare occurrence and would justify action at the time of injury.

Extreme hemathrosis does occasionally demand aspiration of the joint. Nerve symptoms occurring at the time of injury do not constitute an indication for immediate operation.

Ollier maintains that operation should be deferred until the eighth or tenth day. The delay is for the purpose of allowing the immediate reaction following the trauma to subside and give the tissues time to gather headway in the direction of repair before subjecting the region to fresh insult and exposure to infection.

In a previous communication wherein the results of 150 operations for fractured patella, performed by numerous surgeons of this city, were compared, I determined that infection following operation was eight times more common in cases operated before the fifth day than in cases after the fifth day following the injury, and that after the fifth day the risk was small. It seems to us that the same rule should hold good for the elbow and that no fracture should be operated upon certainly before the sixth day, and in many cases not until after the lapse of greater time, even more than the ten days mentioned by Ollier. Hereafter, then, when speaking of immediate operation, it is understood that at least six days have elapsed since the injury.

This arrangement permits of the division of operable fractures into two large groups: (*a*) fractures demanding immediate operation; (*b*) old fractures, demanding operation, operation after osseous repair is complete or for pseudarthrosis. (*a*) fractures demand immediate operation (six days): (1) because of interposed tissue; (2) because of the impossibility of holding viable fragments in such a position as to insure a useful joint; (3) because of the nonviability of the fragment; (4) because of persistent nerve paresis or paralysis.

If these nerve symptoms be due to pressure from interposition, the case belongs in Class 2; if due to nerve division, it is properly treated in connection with nerve surgery and will not be discussed here.

To decide whether or not it is possible to hold fragments in such a position as to insure a useful joint is distinctly a matter of expert opinion, and no man is ever justified on purely theoretical grounds and an *x*-ray plate in advising operation upon a recent fracture, unless he has at his command the abundant clinical data which enable him to compare the late results of non-operated fractures with the late results of those which have been operated upon.

(*b*) Old fractures of the elbow are operated upon: (1) because of nonunion, either due to interposition of tissue or not; (2) to increase the arc of motion; (3) because of nerve lesions.

The class of cases operated to increase motion may be subdivided according to whether the object is to provide motion in a practically ankylosed joint; whether it is desired to bring the forearm to right angles with the humerus, even at the risk of losing such motion as there is with the arm in a position which renders the extremity practically useless; or whether an attempt is to be made to increase the arc of motion in an arm having motion through an arc however small, which includes the position where the forearm is at right angles to the humerus.

To decide in the first two classes of cases is an easy matter, comparatively. The arm will not be made worse as far as function goes, and may be improved. This does not take into consideration, how-

ever, in the almost ankylosed variety that, if resection should be resorted to as a primary operation, a flail joint might follow as the result.

To decide upon operation in the class of cases where it is desired to increase the arc of motion in an arm already of fair service, demands the same expert judgment as in the instance of advising operation upon a fresh fracture for the purpose of retaining fragments in place.

Any motion present is precious—to lose any or all of it is disaster—so that here again an operation can be advised only by one thoroughly familiar with the actual final outcome of an operation, such as is proposed in a case belonging to this class.

Olecranon.—Fracture in this region is very often the subject of operative interference, more often than any other break about the elbow. There are three distinct ways of treating an olecranon break; each method being the procedure of choice under given circumstances. There is first, the splint and strapping treatment, and Bardenhauer's extension apparatus; second, the massage treatment; and third, treatment by open operation.

The first two do not interest now.

Operative interference is indicated immediately after injury in cases where there is much tearing of the secondary extension apparatus combined with wide separation of the fragments. This presumes that there is no contraindication of an incidental character, and that the age of the patient is such that the advantage of accurate adjustment is of adequate importance to justify the risk. Most of the patients are adults, although Ajarghi reports the case of a boy thirteen years of age, Abadie a case sixteen years old, and Monnier even reports a longitudinal olecranon break in a boy eleven years of age.

The skin incision which we prefer is the longitudinal cut a little to one side of the olecranon, preferably to the outer side, so that the stitching of the muscle tear may be easy. We do not see any advantage in the "U"-shaped incision used by Ranzi, and object to the division of fascia in this region other than in the direction of the fibers.

It is unnecessary to go into details with reference to the removal of interposed tissue. We prefer to push off in one piece the semi-organized clot adhering to the fracture surfaces, by means of a piece of gauze. The thus exposed bone needs no curetting.

The method of uniting fragments depends on the condition of the injured parts and upon the seat of fracture. All methods resemble closely the operations which have been recommended for repair of the patella.

If the break is transverse, and the periosteum fascia and other soft parts in good condition, chromic gut sutures at either side of the olecranon with reinforcing sutures on the surface, will be found sufficient. It is frequently found necessary to take stitches in the rent at either side, particularly in the anconeus, to the outer side (see Case I). This method is practically the method recommended by Blake of this city for fracture of the patella.

Provided there is much destruction of the tissue which is expected to receive these lateral stitches, it is better to make use of the method recommended by Berger, in 1901, called "cerclage," or circling, a method also used by Quénu.

Berger passes a strong silver wire about the upper fragment. This wire perforates the tendinous insertion of the triceps. In the diaphyseal fragment a transverse hole is bored through which the wire passes. Tightening the wire brings the fragments in apposition. Berger used a longitudinal incision.

The method of periosteal suturing with bronze, as recommended by Piqué in 1906, seems to us inferior to the "cerclage" method of Berger.

Murphy of Chicago, in 1906, modified the Berger operation in that he passed his wire through punctures in the skin, much after the method Ceci used for subcutaneous suture of the patella. There are four punctures at the corners, as it were, of the olecranon. Although the result in the case reported by Murphy was excellent, we are of the opinion that Berger's method is to be preferred. The advantage of the subcutaneous suture is offset in any case where there is ground for suturing by the disadvantage in not being able to remove organizing blood clot and soft parts from between the fragments. It is also impossible to accurately control the position of fragments. These objections in case of the patella were sufficient to practically displace the subcutaneous operation to the favor of the open method.

When a fracture is comminuted, as in the case reported by Abadie and Délage, the condition of the individual case will decide the steps to be taken, whether cerclage or, as was done in this instance with good result, wiring of the individual fragments after drilling.

When the base of the olecranon is broken, the line of fracture is usually oblique, extending down the shaft of the ulna. In such cases, even with slight separation, it is well to consider open operation, because of the great tendency to displacement at the seat of break, and because of the secondary increase in the amount of callus throughout. (See Case II.) This type of break is often associated with other injury, the most common being backward displacement of the head of the radius.

Anterior dislocation has also been observed, as in the case mentioned by Stolle. In the case reported by Prat, the neck of the radius was broken.

Bérard, in 1904, reports three cases, two women at 50 and 79 years and one man of 40. In only one was what Bérard terms the rational treatment, which consists in resection of the head of the radius, carried out. The result was good. In one case Bérard sutured the head of the radius to the ulna, in an attempt to keep the radius in position. Subsequently he was forced to resect.

I am able to add two other cases, men, 27 and 51 years of age. In the younger case the injury was of five years' duration. There was motion amounting to only a few degrees with the limit of flexion at about 135 degrees. The head of the radius was resected and motion obtained from about 70 degrees to 145 degrees. (See Case III.)

The second case sustained his injury six months previous to operation. His arm could be moved about 20 degrees, the limit of flexion being at 100 degrees. The displacement of the ulna was back and out. The operation was seven weeks ago. At the present time he is still under treatment, with passive motion from 60 degrees to 170 degrees; that is, about 110 degrees. Of this fully half causes pain, and voluntary motion amounts to only about 50 degrees, which is, however, to either side of a right angle position. (Case IV.)

Bérard reported a case of double fracture of the ulna and dislocation of the head of the radius. Resection of radius and suture of olecranon gave excellent result. Abadie and Délage report a case similar to Monnier's, in which the upper fragment was divided in two by a longitudinal break. This individual was 40 years of age. We have had a similar case. (See Case V.)

The oblique breaks extending down the shaft are hard to hold, and in our experience chromic gut is not strong enough. The suture material must have greater fixing power, and we therefore consider

delta metal or bone pegs more suitable. In either event the holes bored are to be at right angles to the break.

When operating upon these badly displaced fractures at the base of the olecranon, combined with displacement of the head of the radius, it is well first to resect the radius, then mobilize the ulna, and finally, if conditions demand, divide and resect the olecranon. As a rule this will not be necessary. In the second case above referred to, orteotomy was necessary because of marked angulation in the union of the ulna fracture. We made the mistake by trying to correct the angulation first and subsequently had much trouble in liberating the olecranon.

Old fractures of the olecranon are often operated to increase the arc of motion. In Case V, above referred to, we were unable to move the olecranon and even though the position of the fragments did not seem bad, we decided upon open operation because of the fact that the arm was in a position rendering it practically useless. Not being able to liberate the upper fragment, we resected subperiosteally, but are not in a position as yet to report the final outcome.

Stolle reports three cases of practical ankylosis following too long use of plaster-of-Paris in fracture of the olecranon. Should it be impossible in such cases to improve the condition by forcible manipulation under ether, then resection would be considered, a subject beyond the scope of this paper. The data to be found bearing upon the results of operation upon old fractures of the olecranon with wide fibrous union and restriction of motion, especially of extension, are scant, and personally I have had no experience with this type.

Ajarghi reports a case in which the fragment had retracted 8 cm. at the end of six months. As it was impossible to bring it down, strands of the triceps tendon were united to the periosteum of ulna. The final outcome was satisfactory.

The same author mentions another interesting case where four months after oblique fracture of the olecranon, not operated, a sharp, bony protuberance caused so much pain on motion that osteotomy and removal of the exorboses became imperative.

After operating, whatever the method employed, it is well to place the arm in some retention apparatus at an angle which represents the maximum amount of flexion possible without putting strain on the suture. This angle will be found in fresh cases to be about 160 degrees, and in older breaks nearer complete extension. Massage should be commenced as soon as the stitches are out and passive motion at the end of two weeks. However, passive motion must be conducted with great care in case of the olecranon because of the amount of leverage on the long forearm, while to the short lever is attached the triceps. We have recently had the unfortunate experience of reseparating the fragments by passive motion. This caused practically no pain to the individual.

As a rule, it is safe to permit patients to return to their occupation at the end of two months. There is apt to be some limitation of extension, but flexion is satisfactory even in the cases where the olecranon was comminuted. Union is bony, as a rule. We have not been able to find a case where after operation the union stretched and thereby indicated the fibrous character, although we see no reason why this should not occur occasionally, just as in case of the patella.

Routier mentions an interesting case where refracture occurred nearly two years after suture of the olecranon with silver. The wire was shown by the x-ray plate to be broken. After this refracture a good result was obtained by massage, and Routier raises the question whether bony union had ever existed—a query which is justified by the repeated observation that the presence of metallic suture material seems at times distinctly to retard the progress of bony union.

Coronoid.—We have been unable to find any case of coronoid fracture which necessitated operation. Scattered cases of fracture of the process are reported, but in none was there any indication to interfere by open operation.

Radius.—Fractures of the head and neck of the radius are operated upon to remove a nonviable fragment acting as a foreign body in the joint and interfering with motion, or to place and maintain a viable fragment in such position as to insure a useful joint. When there is a nonviable fragment the line of break may be transverse through the neck, with or without division of the head into two fragments by a fracture in the coronal plane.

In another group there is no transverse break of the neck, the line of fracture being in the head alone. A small piece may be chipped from the margin of the head, or a large part of the head with the anterior portion of the neck may separate. The displacement of the fragment is in the vast majority of the cases anterior. Operative cases have been reported by Prat, Rèchon, Destot, Vallas, Latarjet. Prat mentions a case of this sort operated upon in which the displacement of the head was outwards. Displacement does occur in other directions than anterior and external, but we are not familiar with any cases which have been operated, except the above and two personal observations, one of which belongs to this class: Male, 29; fall on extended hand; limitation of flexion and extension to a few degrees; arm at right angles; displacement anterior; two fragments of head; transverse of neck. (Case VI.)

The reason for operating is the great limitation of flexion and extension with moderate limitation of prostration and supination. Where the fragment is displaced anteriorly and inwardly, lying at the side of the biceps tendon, as in Latarjet's case, the incision is best made immediately over the fragment at the inner margin of the supinator longus. If the displacement be outward, as in one of Prat's cases, the fragment lies beneath the skin and is easily removed. After removal of the head it is always well to smooth the end of the radius. In the class of cases where it is impossible to retain a viable fragment in such position as to insure a useful joint, the fragment is wedge-shaped, anterior, and attached to some portion of the anterior part of the neck. The fragment stands off, as it were, in some cases being at right angles to the neck. These fragments, although viable, being connected to the remainder of the radius by periosteum, cannot be returned to their normal position, because of interposed tissue, and inasmuch as the faulty position is associated with great limitation of motion, they had better be moved. The incision in these cases is best made over the outer side of the head of the radius. We recently operated upon a case of this sort, male 31, who had limitation of flexion to about 60 degrees, and limitation of extension to about 135 degrees. The limitation of extension was found to be due to adhesions passing between the seat of fracture and the capsule just above the eminentia capitata, and widening of the head of the radius, combined with thickening of the anterior portion of the joint capsule in this region. (Case VII.)

Lane of London reports a case of split in the radial head and neck, in which he obtained a good result by wiring the fragment in place, a unique pro-

cedure, as far as I am able to ascertain. In such cases of fracture of the radius as are operable, there is always much limitation of motion, and, just as in operable fracture of the olecranon, the results here are very satisfactory, there being in most cases almost complete restoration of motion. Limitation of pronation and supination persists longer than that of flexion and extension. Removal of the head does not seem to influence the strength of the joint, and is not followed by valgus deformity. In fact, it has been observed and shown by Prat, in one of his cases, a man twenty-four years of age, that there may occur quite a remarkable formation of bone to replace the lost head. Prat's case was examined by *x*-ray four months after operation. This corresponds to what is well known to occur in long bones deprived of physiological opposition; the bone lengthens.

In the case of a man twenty-seven years of age who had a posterior dislocation of the radius for many years, we resected the head to increase motion. This head, instead of being concave on top, was convex, conical as it were, projecting about half an inch beyond the usual margin of the head.

We now turn to a far more difficult class of fractures, those of the lower end of the humerus, and shall consider, first,

The External Condyle.—Cases of fracture of this portion of the humerus which demand operation are not common. Monnier, Piechaud, Koenig, Starr, and Beck have reported cases, to which I would add a further observation (Case VIII.) Immediate operation may be demanded, because of such vicious displacement that it is impossible to return the fragment to its proper place, because of nerve involvement, or because a small chip has been broken off and acts as a foreign body in the joint. This condition which Koenig calls attention to may initiate secondary changes in the joint. The rare cases of fracture of the capitelum itself belong in this group. They are surgical curiosities with which we, personally, have had no experience, and about which we know nothing, except what has been reported by Hahn, Kocher, Steinthal, and Cotton. The case records are to be found in the publications of these authors. When the fragment was loose it was removed with good subsequent result.

In Steinthal's case the capitelum was displaced up and anteriorly on to the external condyle, and firmly fixed. Motion amounted between 135 degrees and 150 degrees. After resection and removal of the head of the radius the motion was from less than 90 degrees to 160 degrees—a very satisfactory result. Kocher's cases are well known, and the original communication by Hahn in 1853 is of interest because of the fact that four years after the injury, which with the resulting deformity is accurately described, Hahn procured on autopsy the specimen, the only one in existence, as far as I am able to ascertain.

When the external condyle, as a whole, is broken off, the fragment generally having a small piece of trochlea, it is usually displaced up and back, or up and anteriorly. Cases of this variety have been mentioned by Piechaud of France and Starr of Canada. Our case was a boy of seven. The condyle was completely rotated out, so that the fracture surface was beneath the skin. This fragment was attached by a few strands of periosteum only (Case VIII). It was removed through an external incision, as in the similar cases reported by Kocher and Beck.

At the present time—six months after the operation, which was performed July 14, 1906, two weeks after the injury—there is no limitation of motion, and no increase of valgus or lateral motion. Even when on operation it is possible to replace the fragment, it may be difficult to hold it there, as in Koenig's case where the displacement recurred immediately. In our case, there were fibers of the anconeus attached, and we are of the opinion that part of the mechanism of the cases where rotation of the fragment occurs is due to contraction of this muscle. In Starr's case, where rotation was not complete, the displacement present was rotation upward and forward of the articular surface. If the displacement had been carried a little further the fragment would have been in the position reported in Kocher's, Beck's, and in my own case.

In old cases in which the fragment has healed with marked upward displacement, varus deformity and marked interference with motion, linear osteotomy along the line of fracture may be done to advantage, as in the cases reported by Tilanus, Piechaud, Kocher, and others. The results were satisfactory. In these cases it is unnecessary to suture the fragment in place; the arm is simply put up at an acute angle.

Koenig states that such experience as has accumulated indicates that early operation is absolutely indicated in external condyle breaks, especially with rotation back of the fragment, and supports the statement with the report of several cases operated with successful results. It is of course understood that this remark applies here, as in connection with all other fractures, only to cases presenting irreducible displacement of the fragment. There is no objection to suturing through the cartilage if needs be, even with nonabsorbable material, for it has been shown by autopsy, long after operation, that the wire becomes imbedded in the cartilage and smoothly buried.

If there is faulty position of the fragment there is danger of the musculo spiral being caught in the callus. This demands interference, which may even prove advantageous, as in one of Beck's cases, where the paralysis had existed a sufficient length of time to cause such secondary contraction of the tendons as to demand elongation.

The incision used for operating upon the external condyle depends somewhat on the conditions in the individual case.

If a fragment, such as a piece of the eminentia capitata, is displaced anteriorly and upward, it may be convenient to use an anterior incision along the inner margin of the supinator longus and extensor carpi radialis longior coming down onto the outer margin of the brachialis anticus. The depth of the wound and the presence of vessels and nerves render this approach much more difficult than approach to the posterior surface. We can see no reason, anatomical or clinical, for Ruruik's transverse incision in front.

Access to the external condyle, and in fact to the joint in general, is obtained without any question with greatest ease by Kocher's posteroexternal incision, downward at the side of the triceps, and then inward to the olecranon, the anconeous being pulled down. Weber has suggested a valuable addition in division of the outer half of the triceps to the apex of the olecranon in such cases as demand more room. We have had occasion to use Kocher's incision in connection with Weber's modification, and consider the combination better than the addition suggested by Ollier, which consists in tenotomy of obstructing triceps fibers. Weber's incision is quite adequate for most elbow joint exploration in lesions affecting the outer and middle thirds of the joint. After removal of a fragment, there is no reason for immobilization longer than is necessary to insure healing of the

wound. For self-evident reasons, then, it is essential to institute early passive motion.

The Epitrochlea.—This fracture very rarely demands interference. When operation is necessary it is because the fragment is displaced in such a manner as to interfere with the motion of the joint, or threatens to puncture the skin, and finally because of the ulna nerve. When displaced it may be found in the olecranon fossa of the humerus, as in the case reported by Barbat of San Francisco. In my cases the displacement has been downward. The arm was ankylosed. After fixing in place, motion was obtained from less than right angles to almost complete extension.

Kocher is quoted by Koenig as stating that the displaced fragment, when interfering with motion should be excised. It is certain, judging from such case-records as are available, that if the displacement is allowed to remain for but a few days only, the contraction of the attached muscles makes it almost impossible to restore the fragment to its usual position. One very good reason for suturing this fragment in place is that the ulna nerve is very apt to cross upon the line of fracture. If there is much displacement, there is more callus, and therefore danger not only of having the nerve caught between the fragment, but also danger of involvement in the surrounding callus.

It is easy and tempting to approach the condyle from in front, but inasmuch as the position of the ulnar nerve is one of the main reasons for interfering, and because of the fact that even when not caught in callus or between fragments, habitual recurring dislocation of the ulna nerve has been observed secondary to valgus deformity and callus. It is, therefore, wise to approach from behind, and, after restoring the epitrochlea to its place, safeguard the nerve in such a way that this accident cannot occur.

Internal Condyle.—It is an extremely unusual occurrence to be obliged to operate upon an internal condyle fracture as such, and find on exposing the seat of injury that there is no other involvement of the humerus. We have operated twice for presumably internal condyle alone, and on operation found that the line of fracture was not confined solely to the thin section of the humerus. These cases will be referred to later. (Cases IX. and X.) Shiller operated because a fragment broken from the trochlea interfered with motion of the joint, and Weber successfully replaced an internal condyle which was badly rotated back and could not be held in position.

Hoffman has called attention to the fact that, although the amount of motion in the joint may not be considerably interfered with, yet the varus deformity consequent to union of the internal condyle in a faulty position, interferes greatly with the carrying power of the arm. With the exception of an occasional operation because of nerve involvement, most of the internal condyle injuries operated upon are old cases, with marked varus. Such have been referred to by Derscheid, Delcourt, Kocher, Tilanus, Koenig, Piechaud, and Davis of Philadelphia. Davis mentions three cases in which he obtained good results. The operative procedure advised by him is the application of McKewen's operation on bow legs, to the elbow. A fine osteotome divides the humerus, above the joint on the inner side, to the extent of half the diameter of the bone. The remainder is broken, and the arm put in the normal position. Any attempt to proceed by osteotomy in the line of fracture, with subsequent replacing of the fragment, involves much division of soft parts, combined with opening the joint, which, to our way of thinking, is a risk quite out of proportion to the probable advantage gained. This procedure can be made use of only in cases where an internal condyle, having united in faulty position, has led to the formation of sufficient callus to provide great limitation, or fixation of the arm in a position, rendering the extremity practically useless. The faulty position itself, without excess of callus, may be productive of this degree of disability. Stimson is of the opinion that the varus deformity is largely due to a dropping down of the fragment in external breaks because of the right angle position—the forearm rotates with this fragment in the sense of supination. The excess of callus filling the gap is then responsible for the subsequent deformity. In internal condyle breaks, Stimson believes that there is a transverse break through the lower end of the humerus, and that the excess of bone is again found on the outer side. In both instances this authority prefers a wedge-shaped osteotomy on the outer side, a preference surely justified by the pathology of the injury.

The method of approach when operating upon recent fractures of the internal condyle is not a matter of indifference. As already mentioned, the anterior approach, along the inner margin of the brachialis anticus, gives easy access to the internal portion of the condyle and to the epicondyle, without opening the joint. However, the wound is deep, and many vessels are encountered. Inasmuch as safeguarding the ulna nerve must also be thought of, besides replacement of the dislocated fragment, it seems to us that the posterior route is better suited, the incision being carried down close to the triceps, leaving the ulna nerve to the inner side. In a few cases, such as that reported by Brun, where a very oblique internal condyle fracture produced symptoms referable to the median nerve, one might be obliged to prefer the anterior incision. We have tried both, and prefer the posterior route, because of the fact that in children, especially, one may discover on operation quite an unexpected comminution and displacement of the cartilaginous portion of the humerus, demanding an extension of the incision, which will be discussed in connection with dicondyle and comminuted breaks. We prefer to hold the fragment in place by means of chromic gut sutures passing through drill holes perforating shaft and fragment anteroposteriorly, unless, after placing the forearm in position which it is to occupy, it is found that the unavoidable pressure on the fragment is in excess of what might reasonably be expected of the gut until the time for passive motion massage arrives.

When there is difficulty in retaining the fragment, bone pegs may be preferred. Princeteau has used the latter with success, and calls attention to the fact that there is ample clinical evidence that metallic suture material may tend to delay union; cases bearing on this point having been published by Stephen Waltz of Baltimore, Dujarrier, Courtin, and others. It would seem that whenever more resistant material than gut is demanded, bone or ivory pegs should be resorted to in preference to wire or screws.

Supracondyloid Fracture.—Although this is comparatively a common break, at least the extension variety, immediate operation is rarely indicated, and in this event is usually resorted to because of the interposition of tissue. The nerve injuries will be referred to later. The brachialis anticus is the common offender in cases in which the diaphyseal fragment pierces the muscle.

Bolles and Lund of Boston have operated upon recent cases with good result, and Lane has called attention to the fact that the triangular fragment of diaphysis adhering to the posterior part of the lower fragment in extension breaks should be carefully preserved, as of value in holding suture material. In my cases the obliquity of the break was not sufficient to affect materially the holding of suture material. No case of operated flexion break has come to my notice.

Most of the reported operations were in old cases which had been allowed to heal with the lower fragment of the humerus in faulty position. That exuberant callus in the anterior region of the joint may interfere with flexion because of opposition to the coronoid process is well illustrated by the cases reported by Mouchet, Kirmisson, Bardenhauer, Tilanus, Monnier, Tuffier and Beck. In children exostoses forming about the line of fracture may be the cause of interfering. When dealing with callus masses limiting flexion one should remove until the coronoid process is not obstructed, even if it is necessary to perforate the humerus. Stimson believes that much of the limitation of motion is caused by the changes in the muscles—particularly the triceps.

When there is motion with the arm in a relatively useless position, as in one of Stommer's cases, excision of callus may be of advantage and result in great improvement. In the instance above referred to the patient could finally flex to 90 degrees with very little limitation of extension.

Cotton has called attention to the frequency of varus deformity after supracondyloid breaks. The method of treating this deformity has already been referred to. Yudet has shown in a series of cases that, although varus is more common than valgus, still the latter is not an uncommon occurrence, and may even be sufficient to demand operation, as is well shown by a case reported by Tilanus.

Whenever complete ankylosis is found after supracondyloid fracture, little is to be expected from any operation which aims at regaining motion without loss of bone. In such cases excision of the displaced fragment is to be preferred.

Partial resection will be referred to in connection with dicondylar and comminuted breaks. There is some difference of opinion as to the best incision for treating supracondylar breaks. Lane and Monnier have used anterointernal incisions with success; Tuffier and Tilanus, anteroexternal incisions; and Gaudier resected a badly displaced lower fragment of a supracondylar break through bilateral incisions, such as are recommended by Nicoladoni and Eiselsberg.

We are of the opinion that the anterointernal incision gives best access to callus obstructing the coronoid process; that for the purpose of liberating the lower fragment preparatory to resetting and fixation, Kocher's posteroexternal incision, or with extension to the tip of the olecranon, as done by Weber, and that for partial resection—this same incision should be first tried, and, if found insufficient, it may be combined with an anterointernal incision.

This combination of posteroexternal of Weber, and anterointernal, gives the greatest access, with the minimum amount of damage to vessels and muscles, and at the same time avoids all of the nerves, median, radial, and ulna.

Dicondylar and Comminuted Breaks.—Many of these cases are compound, the force producing so extensive an injury being sufficient to drive the fragments through the skin. The doubtful prognosis as to function following injuries of this character is well known, and it is therefor that we examine with more than usual interest cases such as are reported by Bristow of Brooklyn, Starr of Canada, and Tuffier.

Bristow operated upon a dicondylar break with comminution of the trochlea and sutured the remnants of the condyles "as best he could." The ultimate result gave 4/5 of the normal range of motion. Starr operated through a Langenbeck division of the triceps, removed several pieces of bone, and wired the condyles separately to the shaft, obtaining a final result of about 90 degrees motion. Tuffier reports two cases of "T"-fractures without comminution, the triceps interfering with reduction. In both he transfixed the condyles with calf bone pegs and obtained excellent results.

We would add a further observation: A boy of fourteen years of age, with a Y-fracture, and division of the internal condyle, into two pieces, because of separation along the line of the epiphyses. The upper triangular piece was dislocated backwards, penetrating the triceps, and being stripped practically free of periosteum, was removed. The remaining fragments were sutured with chromic gut. Six weeks after the injury he had flexion to 60 degrees and extension to about 130 degrees. (Case IX.)

In this instance we made use of Langenbeck's longitudinal division of the triceps. The reason for operating was the impossibility of reducing the fragments. On the strength of observations such as these, we believe that in dicondylar breaks, and other comminuted fractures, one should operate immediately when it becomes apparent that the fragments cannot be properly held in place. Having used Kocher's posteroexternal incision with Weber's division of the outer half of the triceps repeatedly in other types of fracture, we are of the opinion that this incision is preferable in ordinary cases to either the posterointernal or Langenbeck's incision.

In cases where the amount of destruction is very great—as in Case IX. of my series—we believe that the following modification of the Kocher posteroexternal incision is to be preferred to Weber's. The incision is carried to the side of the olecranon and the olecranon divided and turned up. This incision completely exposes the entire joint and allows easy access to every part. When the maximum trauma is on the inner side the vertical portion can be made on the inner side, but even if made to the outer side this method exposes most satisfactorily the inner condyle. We have tried these incisions and found the exposure most satisfactory, and feel that we can recommend this procedure, but only in cases where the damage of the primary trauma is so great that the question is whether or not resection of the lower end of the humerus is to take the place of adjustment of fragments. The additional division of the olecranon in such cases is a small matter compared with the problem present in the lower end of the humerus.

Volker and Trendelenburg have used the transverse incision with liberation of the ulna nerve, and Tilung modified this by going through the tendon of the triceps for the purpose of being able to use a flexed splint. The disadvantage of the latter method needs no comment, and we agree with Weber that the modification of Kocher's incision, by dividing the outer half of the triceps, is also preferable to the transverse incision with division of the olecranon. In the extreme cases the combination of longitudinal incisions with division of the olecranon gives the best exposure.

We understand that in comminuted breaks Weber recommends primary resection of the lower end of the humerus. It does not appear that cases such

as the above referred to justify so radical a procedure. Especially in children it is essential to remember that improvement is always possible far and above what theoretical considerations might lead us to expect. We are of the opinion that in children where the epiphyses are still active, even partial resections are to be avoided unless it would mean leaving the arm in a practically useless position not to do so. In adults Weber's proposition can be resorted to with advantage much more freely.

Orthopedic resection of the elbow, for ankylosis in adults, is the last resort. It is best done at the level of the lower margin of the head of the radius. Abadie claims that arthrotomy and partial resection have no place in these cases, notwithstanding the views of Nélaton and Kirmisson. It is his opinion that ample resection gives far better results.

We shall omit any reference to the technique of excision as being too extensive a subject to enter into.

Separation of Epiphyses.—Injuries of this type demanding operation are very few. It occasionally happens that the separation of epiphysis is carried far back, and with such effusion, into the joint as to make reduction of the fragment impossible. This happened in Princeteau's case. Separation of the component parts of the epiphyses, with displacement of the ulna, is another cause for immediate interference.

Tuffier reports operating for this condition with good result, a month later motion being very slightly limited. Dollinger recommends immediate operation when other methods fail to hold the epiphysis in place. I have operated upon a boy 2½ years of age who appeared to have a break of the internal condyle which could not be reduced. On exploring it was found that the trochlear epiphysis had separated from the condylar epiphysis and that the trochlea epitrochlea and triangular piece of diaphysis formed one piece which was tilted upwards anteriorly. Even after exposure it was impossible to push the diaphyseal fragment into place until the internal intermuscular septum had been divided. After this the diaphysis was drilled and the cartilage sewn into place. (Case X.) The *x*-ray plate in this instance gave no evidence of the displaced portion of the epiphysis, because trochlea nucleus does not show at that age. The nucleus of the condyle showed in its proper relation to shaft and upper end of radius. At the end of fourteen days passive motion amounting to 45 degrees was obtained.

When marked limitation of motion follows union of a displaced epiphysis in faulty position, it is necessary to expose the region and replace the fragment. This has been done successfully by Broca and Monnier. In Broca's case the result was good, but in Monnier's it was not satisfactory as to function, the injury having occurred in a paralytic arm. There is no doubt that the bone pegs are most suitable to fasten these epiphyseal fragments in place, provided there is no possibility, as in the author's case, of suturing with chromic gut.

Félizet calls attention to the fact that after epiphyseal separation at the lower end of the humerus, it is not uncommon to have exostoses develop just above the epiphyseal line. This author reports three such observations. There was much limitation of motion, which was completely relieved by the removal of the bony outgrowth.

The incisions necessary for convenient approach to these regions have already been considered.

In the treatment of all operative fractures, there is one thing to be remembered, namely, that the operation is only half of the treatment, the other half being careful prolonged orthopedic after-treatment, and that the first without the second is apt to result in failure. Early massage, early and frequent passive motion, and discarding of all fixing apparatus just as soon as the conditions of the individual case permit, should be the aim of post-operative care. Passive motions must not be carried beyond the point of pain, otherwise a sprain is produced.

Nerve injuries following fracture at the lower end of the humerus are not uncommon. In Von Brun's statistics of 58 cases of nerve lesions of the upper arm, thirty-three are due to injury at the elbow, the order of frequency being musculospiral (radial), ulnar, and median. Broca and Mouchet emphasize the frequency of nerve lesions in supracondyoid breaks. Of thirty-five cases, seven had nerve complications. Primary division of all three nerves has been observed.

Payre reports recurrent dislocation of the ulnar nerve due to valgus deformity. Paralysis may be primary, secondary, or late. Primary is never the cause for interfering, inasmuch as compression cannot be distinguished from division. Secondary paralysis should always be operated, and, of course, primary, which does not improve. Even when primary ceases to improve, operation is indicated.

The details of treatment are beyond the scope of this paper. Neubauer states that the prognosis is good under proper operative care, which corresponds to the statistics of Kramer, quoted by Reisinger. Of thirty-five cases there were only three with absolutely unsatisfactory results. Bush reports a case of complete recovery after sixteen months. We have liberated the ulnar twice, the median and musculospiral once each. Both ulnas regained function, the median showed no improvement, and the musculospiral some improvement.

According to Kramer, the average time for recovery is one year, and, inasmuch as the last two cases have been operated only about four months, there may be some improvement yet.

Reithous emphasizes that primary paresis, not increasing, should be treated expectantly. We consider that the expectant form of treatment also applies to secondary paresis, having seen ulnar paresis occur, deepen, and finally disappear in the course of a supratrochlear fracture. Lambert reports an interesting case of late ulnar paralysis following a neglected olecranon break, with increase in size of the fragment and exostosis as shown by *x*-ray. Most late ulnar pareses or paralyses are secondary to extreme valgus deformity.

Secondary muscle symptoms have been reported by Littlewood of England, but inasmuch as the symptoms described correspond to those seen after the use of too tight apparatus, and inasmuch as Littlewood states that the majority of the ten cases he reports had pressure sores, we consider that the condition is to be laid not at the door of the fracture, or even to the unavoidable muscle changes, but rather to a disregarding of the fact that severe injuries have severe swelling and must be bandaged accordingly.

Whether Bier's autoinjection of blood between the fragments of non-uniting bones can be made use of in elbow fractures remains to be determined. Loehrer has reported success in the treatment of a leg fracture. Observations to the effect that venous hyperemia increases the size of bones, date back to Stanley, in 1849; Paget, 1853; Broca, 1856; but whether Bier's artificial hyperemia by autoinjection treatment will be possible in the region of a joint has, as already mentioned, not yet been determined.

In closing, may I call attention to the fact that the above remarks on operative treatment of fractures about the elbow apply only to cases where there is no doubt whatsoever about the advisability of operation in a given case. When there is doubt it is best to wait. Even when particularly interested and keenly alive to the disastrous effects of meddlesome surgery in this region, one must still bear in mind the fact so tersely put by Mouchet: Time often proves the best and most economical surgeon.

Case I.—M. R., female, 26; September 23, 1906, hit arm on back of chair; fracture of olecranon, nearly transverse, with ¾-inch separation. On examination under ether, inability to force fragments together completely. September 29, incision to outer side of ulnar; blood clot from between fragments removed. Lateral tear in anconeus, with laceration of muscle. Lateral chromic gut sutures in capsule and muscle interrupted, plain gut. October 9, stitches out. P.P. union; passive motion. December 28, motion; sl. limited in flexion and extension. Still improving.

Case II.—J. W., 61; February 17, 1906, coming downstairs, fell and hit elbow. Treated ten months in right angle splints. December 19, 1906, few degrees of motion in elbow; backward displacement of radius. Callus on ulnar 2 inches from tip of olecranon; angular deformity. Posterior incision along callus, osteotomy, in line of fracture which involves lower part of joint. Ulnar straightened. Olecranon firmly adherent. Mobility with aid of strong, sharp hook. Ulnar wired with silver external incision, and resection of head of radius. Arm put up at 160 degrees. P.P. union. Motion at end of five weeks 90 degrees to 160 degrees; no increase in extension beyond what was present after straightening elbow at time of operation.

Case III.—October 25, 1905. M. McE., male, 27; five years ago, fall, method of landing unknown. Position: forearm semiprone. Flexion at elbow limited at 135 degrees, about 15 degrees extension. Very little pronation and supination. Bony deformity in region of olecranon; convex posteriorly; head of radius displaced backwards, close to side of olecranon. October 27, 1905, head of radius resected. November 3, 1905, stitches out, P.P. union. November 8, 1905, passive motion. November 30, 1905, motion, 70 degrees to 145 degrees.

Case IV.—P. M. male, 51 years; fell over backwards, landing on elbow, six months before operation. December 9, 1906; arm at obtuse angle; limitation of flexion at about 100 degrees; amount of motion, 20 degrees. Backward and outward displacement of diaphysis of ulnar on olecranon; angulation slight. Head of radius displaced backward and outward. Operation: Resection of head of radius; brisement forcé of elbow. Put up at right angles. Passive motion tenth day. Seven weeks after operation passive motion from 60 degrees to 170 degrees, one-half of which is painful; about 50 degrees voluntary motion, including position at right angles.

Case V.—J. B., 62; about one year ago fell and hit elbow. At present time much thickening about olecranon. Arm at obtuse angle with few degrees of passive motion, if forced. January 25, 1907, incision to outer side of olecranon. Old oblique fracture downwards and outwards from base of olecranon. Attempts to move arm failed before incision resorted to. Longitudinal division of triceps, insertion and subperiosteal exposure of olecranon which was found to be divided longitudinally by callus indicating seat of fracture. Olecranon fragments removed subperiosteally; outer fragment included a piece of coronoid. The intraarticular adhesions were very firm, binding the olecranon fragments firmly to the humerus. P.P. union. As yet no passive motion tried.

Case VI.—F. S., male, 29; August 12, 1906. Five days ago fell "with arm under him, and extended." Exact method of landing unknown. Slight swelling; limitation of motion in every direction; arm held fixed at right angles. *X*-ray plate shows neck of radius broken transversely and head divided into two pieces; one piece displaced anteriorly and inwardly—the smaller; the larger, anteriorly and out. Both pieces rotated so that articular surface faces outwards. External incision; pieces removed. P.P. union. Passive motion tenth day; discharge on twenty-first day, with flexion from 140 degrees to about 70 degrees. Pronation and supination one-half normal. Has not been examined since.

Case VII.—M. L., male, 34; October 12, 1906. Five weeks ago, fall on hand, followed by swelling of elbow. Arm treated in right angle splint. At present time, marked limitation of pronation and supination. Extension to about 135 degrees; flexion to 60 degrees. Thickening in region of head of radius. Operation: External incision; splint in coronal plane of head and neck of radius. Head widened anteroposteriorly. Firm adhesions to capsule just above eminentia capitata. Anterior part of capsule thickened. Adhesions removed and joint moved. Flexion, pronation and supination limited by increased anteroposterior lengthening of head. Piece chipped off by injury removed. P.P. union. December 17, 1906: Extension normal; flexion very little limited; pronation normal; supination the same as before operation, that is, much limited.

Case VIII.—W. M., male, 7; June 21, 1906, fell from ladder, hit on elbow. *X*-ray shows complete rotation of external condyle; fragment not easily moved; cannot be reduced. Motion, limitation in every direction. July 14, 1906, external incision, immediately over fragment, which is slightly displaced anteriorly; removed easily. Fibers of anconeus attached—divided. Fragment has small piece of trochlea. July 24, 1906, stitches out; P.P. healing. July 26, 1906, wound solid; passive motion. January 21, 1907, no limitation of motion; no increased lateral mobility; no valgus deformity.

Case IX.—R. H., male, 14; November 17, 1906, swinging on parallel bar, slipped, fell backward on elbow; much swelling. November 21, *x*-ray showed internal condyle divided in two fragments; external condyle broken off; line of fracture joining internal line of break, at about line of epiphysis. Whole lower end of humerus tilted to inner side and displaced up. Diaphyseal fragment of internal condyle rotated back and displaced. Considerable separation between other fragments. November 29, 1906, operation, Langenbeck incision; diaphyseal fragment projecting back into triceps removed subperiosteally; remaining fragments sutured with chromic gut into place. Method of exposure, bad. Arm put at right angles. December 8, dressed; P.P. union. December 12, 1906, passive motion. January 27, 1907, motion from 60 degrees to 130 degrees. Resistance, elastic. Much thickening about lower end of humerus. Region of excised bone filled in.

Case X.—J. McM., 2½; January 10, 1907. Two days before entrance, fell; hit elbow. Direct violence. P.E.: Much swelling of whole elbow; motion limited in every direction because of pain. *X*-ray shows internal condyle break with upward and backward displacement. Reduction impossible.

Operation, January 14, 1907. Anterointernal incision at side of brachialis anticus. Line of fracture through internal condyle to diaphyseal line, then along diaphyseal line outwards, and finally obliquely through outer part of trochlea. This fragment is tipped forward below and backwards above, being displaced as a whole inward and upward. *X*-ray plate showed only backward and upward displacement. An attempt to push fragment down unsuccessful, until internal intermuscular septum divided, then fell easily into place. Diaphysis bored and fragment fastened in place with No. 4 chromic gut, passed through cartilage in epitrochlea region. P.P. union. Passive motion ten days; at end of fourteen days 45 degrees motion. Note: Seen February 6, 1907; motion about 60 degrees.

THE ADMINISTRATION OF PROTEIDS IN TUBERCULOSIS.

By GEO. HEYDE KRALL, M.D.,
LANSDOWNE, PA.

THE nitrogen that enters into all forms of life is the most important constituent of our food. Every tissue and organ owes its reconstructive and formative properties to this element, which is contained in the proteids. It has been clearly demonstrated that in a very short time after the absolute omission of proteid from the food, life becomes extinct. If this form of food did not exist, life in its present form would cease and a new form would possibly come into existence whose laws of reproduction, growth, nutrition, and decadence would be entirely different.

With the normal healthy individual there is a constant utilization of protein matter required in growth and repair. Our every mental effort or muscular action consumes some part of our total available food or tissue supply. While energy may possibly be better derived from the other forms of foodstuffs, the tissue to be replaced must have this nitrogenous element. In disease the tissue destruction is naturally greater, and the constructive requirements, under most pathological conditions, are decidedly increased over the normal.

It is surprising how little proteid is necessary for the maintenance of body activities. Chittenden,[1] in his painstaking experiments upon himself, showed that less than forty grams sufficed to maintain the body during a long period of considerable mental activity. It is true that exercise demands a greater supply of proteid, but not so much as might be supposed. In observations made upon athletes and soldiers performing a great amount of work, fifty-five grams were found sufficient. In tuberculosis the patients exercise to only a comparatively small extent; although they excrete a slightly increased amount of nitrogen, they do not require as much as the normal active individual.

The figures of Chittenden are far below those given to us by any other investigator. This may lead us, upon superficial observation, to doubt their value; but when we compare the exhaustive and thorough methods of this observer with those of others, we are quite convinced that accuracy and thoroughness are all on the side of his experiments. No investigators have made the painstaking and convincing experiments that have been performed by Chittenden. His work should be a monumental guide in our treatment of this disease, tuberculosis. This author brings clearly before the practitioner the important fact that economy should be practised in the administration of proteid, and indeed leads us to believe that there is considerable danger in giving an excessive amount. The tendency of recent scientific observation, based upon more thorough methods, leads us to believe that the ingestion of excessive amounts of proteid in the treatment of tuberculosis is not only unjustifiable but harmful. This opinion is held by Folin,[2] who seems to have a keen insight into the demands of the economy. His observations have been confirmed by others, who show that the organism thrives and continues in a state of nutritional equilibrium when but small quantities of proteid are administered.

Unfortunately, advantage has not been taken of these recent advances in the treatment of tuberculosis. Nothnagel[3] recommends the consumptive to take in excess of one hundred and twenty grams; Thompson[4] states that in the sanatorium at Bridge-of-Weir, the diet, until recently, contained one hundred and fifty grams of proteid, but of late there

has been a very slight reduction from this amount. The amount of proteid recommended by the various contributors to this subject varies from one hundred to one hundred and fifty grams. Many authorities increase the total amount of food intake to as much as six thousand calories, and increase the amount of proteid proportionately. At a sanatorium in this country the individual is given a diet consisting of an increase of 10 per cent. over that required by a healthy man at hard labor.

In the various sanatoria there are definite methods of feeding, and in nearly every instance the exact energy-producing value of the diet is carefully estimated. However, in private practice the physician is frequently anxious to increase the amount of nourishment given the tuberculous patient. He supplies large quantities of milk, eggs, meat, and other forms of nutritious foodstuffs, with no regard for the proteid content; and it is very likely that many persons with tuberculosis treated under these conditions ingest a very much larger content of proteid than one hundred and fifty grams daily. To illustrate this I would cite a case reported by King[5] of a young man whose physician advised him to eat all the meat and as much milk and raw eggs in addition as he could stand, and King roughly estimated that this patient was daily taking into his stomach three hundred and seventy-five grams of proteid with a corresponding increase of the other constituents. It has been clearly demonstrated that the normal individual requires a quantity of proteid far less than that recommended by these authorities. Reasoning upon a similar scientific basis, the same facts apply to tuberculosis.

It is commonly believed that more proteid matter is needed in diseases of a wasting nature, such as tuberculosis, than in health; and while this may be true, at the same time we are apt to neglect the fact that a normal individual leading an active, healthy mental and physical life, such as those reported by Chittenden, require nearly or fully as great a nitrogen supply as the tuberculous patient. It seems probable that only a comparatively small proportion of the proteid is really utilized for the purpose of tissue repair and growth, and the remainder goes to supply heat and energy which could be more readily obtained from the easily oxidizable fats and carbohydrates.

Even more conclusive is the fact that proteids are not stored in the body, and when consumed in excess the products of their destruction flood the circulation and have to be eliminated by the kidneys. Folin[6] says that "we clearly have at present no reason for assuming that anything like the one hundred and eighteen grams of proteid demanded by standard diets is either necessary or advantageous." Further, Labbe and Vitry[7] state that in general the power to assimilate albuminous material is subnormal in tuberculous subjects. This is particularly true according to the same writers[8] in the second and third periods of the disease.

A fact of great importance, that should not be overlooked in this connection, is the harmful action of products which result from the partial breaking down of the proteids not utilized by the body cells. The urea, uric acid, xanthin, creatinin, and many other like products certainly have a most detrimental effect and are instrumental in causing many diseases. Circulating in the system, they irritate and cause degenerative changes in the heart, blood-vessels, kidneys, and indeed every active structure. Chittenden[5] says: "We must not overlook the great loss of energy to the body in handling and getting rid of the surplus of unnecessary food of whatever kind introduced into the alimentary tract, to say nothing of the danger of intestinal putrefaction and toxemia when, from any cause, the system loses its ability to digest and absorb the excess of food consumed. Further, the strain on the kidneys and other organs must not be overloked. To an unprejudiced observer, one not wedded to old-time tradition, it would seem as if a great effort was being made to sustain the claims of high-proteid intake. It is surely well to be careful, but it is certainly not necessary to manify imaginary dangers to the extent of suppressing all efforts toward the establishment of physiological economy."

Many authorities assert that the large proteid content is justified on account of the higher percentage of nitrogen eliminated in the urine. This is not primarily due to increased tissue destruction, but rather to a breaking down of the excessive proteid ingested. If in such cases the amount of proteid were lessened, the nitrogen output would be lowered. Drawing conclusions from the facts already given, it is certainly reasonable to believe that the large amounts of proteid usually advocated in the treatment of tuberculosis are not justified physiologically and that they will rather exert an untoward influence on the disease by producing other pathological conditions.

In this connection it might be well to state that certain clinicians have made the statement that the metabolites of proteid exert a specific action upon the disease. French[9] leans to this belief and says that "if the theory that uric acid in the blood antagonizes the tubercle bacilli be true, there is no better way of securing this condition of the blood than by an exclusive meat diet or a near approach to it." Dixon,[10] in his endeavor to substantiate this theory, advances the argument that in lithemia there is an excess of xanthins, and in tuberculosis a deficiency of this series, and consequently favors the administration of such groups as will increase the xanthin output. This may readily be obtained by an increase of the proteid intake, which increases the amount of xanthin formed. Lastly, it is claimed by the supporters of this theory that persons with the uric acid diathesis seldom contract tuberculosis.

It is a well-known fact that the susceptibility to tuberculous infection gradually increases from infancy to the age of twenty-one, from which point the danger of infection decreases. The uric-acid diathesis, on the other hand, does not usually produce manifestations before the age of twenty-one and gradually increases with succeeding years, so that the time of greatest uric-acid involvement is coincidental with the period of minimum danger of tuberculous infection.

This demonstrates that the infrequency of tuberculosis in lithemia is purely incidental. Indeed, as we carefully scrutinize the statements of these men we find that they advance arguments of a like nature, too general in character to have a scientific meaning, and in no way showing that the end-products have any beneficial effect upon the progress of the disease. This means that advocates of the theory must rely mainly upon clinical evidence rather than scientific reasons. But even here the bulk of the medical profession have not substantiated their observations.

Recently investigations have been made by numerous experimenters[11] upon animals in which an Eck fistula has been established. By this means the portal circulation is deviated from its regular circuit and the blood is sent directly into the vena cava. The portal blood, in consequence, does not flow through the liver. Under these conditions ammonium carbamate, an antecedent of urea, is formed, the result

of proteid catabolism. This metabolic product is extremely poisonous, causing convulsions and even death. Although urea, which is normally formed, is not nearly so poisonous, yet in large doses it is certainly pernicious in its effects upon the activity of the various organs. The ingestion of much proteid means an increased amount of urea production, with its concurrent tendency to these effects. But there is also formed—the result of the breaking down of the ingested proteids—other substances which, although produced in comparatively small quantities, are far more powerful in their poisonous action than urea. Creatin and creatinin belong to this group, and have been found by Mallet[12] to have a decided pharmacological action, their most marked effect being a retardation and depression of the heart. Another substance of like nature is adenin, one of the purin bases, which, according to Minkowski,[13] exerts a most toxic action upon the circulation.

It need hardly be mentioned in this connection that uric acid, which is markedly increased in quantity when the proteid intake is great, also has a detrimental effect. The uric-acid diathesis, lithemia, and gout are all directly or indirectly attributed to an excessive amount of this compound in the circulation. Allbutt and Rolleston,[14] considering the products of proteid destruction in general, state that they produce high blood-pressure, arterial degeneration, and renal disease.

When these facts are taken into consideration, it is certainly dangerous to increase the amount of proteid in the diet, even though the nitrogenous waste products in the economy may have a specific action. The scientific evidence in this connection does not justify us in accepting the empirical conclusions of a few clinicians. It is manifest, when all the facts are studied from a physiological standpoint, that excessive proteid diet is useless, as has been stated by Liebermeister[15] and Ebstein:[16] and when pathologically considered a detrimental effect seems more than probable.

When we take into account that it is possible for the normal individual at hard work to retain his full mental and physical vigor on an intake of fifty-five grams or less of proteid daily, it is a matter of wonder that the increased metabolism of proteid matter that is usually expected of the tuberculous patient is not more disastrous. The energy consumed in the system in the digestion, absorption, and elimination of almost three times the amount normally required, certainly constitutes an additional drain on the patient's already weakened and overtaxed store of activity.

While we should fully realize the absolute necessity and great value of the proteid content of the daily ration of our tuberculous patient, we should endeavor to keep this amount within the bounds of purely physiological demands and not administer a single gram over this quantity, as determined by the most careful study of the patient's nutritional equilibrium; for every particle of excessive proteid matter given will unquestionably not only interfere with the favorable termination of the disease, but will be productive of pathological conditions which we have been prone heretofore to charge to the account of the tubercle bacilli. It is not beyond reason to believe that there are some cases of tuberculosis that have died of renal involvement, cardiac insufficiency, toxemia, and other pathological conditions whose life might have been prolonged through the proper equilibrium of proteid metabolism.

ADVANTAGES AND DISADVANTAGES OF SIMPLE EXTRACTION OF CATARACT.*

By EDWARD B. COBURN, M.D.

new york.

Before discussing the advantages and disadvantages of the simple method of cataract extraction as opposed to the combined method, or extraction with iridectomy, it is understood that the Pagenstecher or Indian method of extraction (*i.e.* in the capsule) is excluded from consideration. We shall assume that the patient is healthy, the field of operation is normal as to bacterial content, the aseptic precautions are thorough, and the patient is tractable.

In justice to the operation and to the operator certain cases should not be included in any statistical table, as neither one is blameworthy. This refers to very old patients who are liable to pain and shock, hypostatic pneumonia, postoperative delirium, and death from suicide or disease, to dislocated lenses or fluid vitreous discovered after the operation is begun, to collapsed eyeballs (frequent in elderly persons and when cocaine has been too often instilled) and to hemorrhage from the choroid or retina. Nor should cases be included in which the patient is uncontrollable during operation and squeezes the lids, causing escape of vitreous.

Strictly speaking, pyogenic infection should not be charged against a method, though it is customary to do so, liability to infection being proportional to the number of instruments employed and to carelessness in asepsis.

The steps of the simple method of extraction are as follows: (1) Introduction of speculum; (2) section of cornea; (3) capsulotomy; (4) extrusion of lens; (5) toilet of wound, which includes the removal of cortical lens substance and replacement of

*Read before the Section on Opthalmology, New York Academy of Medicine, March 18, 1907.

the prolapsed iris (if it occurs); (6) removal of speculum.

Every step, including the use of a speculum, is debatable, and results may vary according to the judgment of the operator in performing the different steps of the operation. Thus the section of the cornea may be variously placed or include a flap of conjunctiva. The amount of effort made to remove cortical debris and replace the iris may be a potent factor in the result. The speculum may be removed after the capsule is opened or the lens is delivered, or it may be dispensed with entirely.

Having in mind, then, all these variations possible (and all have not been mentioned), let us consider the advantages of simple extraction:

1. There is no unnecessary traumatism to the eye, *i.e.* only such procedures are employed as are absolutely necessary to remove the lens. The burden of proof lies with those who advocate anything more than is strictly essential to the end in view.

2. A minimum of mutilation means a minimum of danger of infection.

3. The number of instruments required for this operation is the smallest possible for removal of the lens. Ordinarily only two instruments are introduced into the eye—the Graefe knife and the cystotome. This may be reduced to one if the capsule is incised during the passage of the knife through the anterior chamber. In some cases a spatula is necessary to reduce the primary prolapse of the iris.

4. The fewer the number of instruments introduced into the eye the less is the liability to infection.

5. The anterior chamber is free from blood and the various steps of the operation are clearly visible.

6. The iris protects the wound from tags of capsule and particles of lens matter; hence these are less liable to get into the wound and cause delayed union, or by their presence act as foreign bodies and excite irritation. Infection, glaucoma, sympathetic ophthalmia, iridocyclitis, and cystoid scar may result from this incarceration.

7. The iris serves as a curtain to prevent prolapse of the vitreous.

8. Simple extraction takes the shortest possible time in removing the lens. Brevity of time means less exposure of the eye to pyogenic infection.

9. No assistants are required to perform simple extraction. The danger of infection is thereby diminished, and there is no fear of prolapse of the vitreous from undue pressure by unskillful assistants.

10. Convalescence is shorter by virtue of less traumatism.

11. The iris responds to stimulus and serves its purpose as a diaphragm in an optical sense.

12. Visual results are better. When the pupil is round, spherical aberration of the peripl ery of the cornea and of the correcting lens is cut off.

13. Some writers claim that the field of projection is better with a circular pupil.

14. Better vision and better projection mean less confusion, and together afford greater safety to the patient.

15. Cosmetic reasons. The result is ideal. The pupil is round and central, and the eye presents a normal appearance. Sensitive persons do not, therefore, suffer by exciting remark and attention.

16. It is the easiest method of extraction.

The disadvantages charged against this method are:

1. The method is not adapted to all cases.

2. The corneal section must be more carefully placed to avoid secondary prolapse of the iris. While this is true, operators who cannot control the location of their corneal section have no right to operate by any method.

3. The corneal section must be larger to permit the exit of the lens as the iris is prolapsed into the opening and diminishes the available space.

4. Capsulotomy is not so easily performed in a small pupil. If peripheric capsulotomy is attempted, the instrument must be out of sight during the opening of the capsule, and, because it is unseen, undue pressure may cause dislocation of the lens and difficulty in its extraction, as well as prolapse of the vitreous. The point of the instrument may become entangled in the iris.

5. More pressure is required to tilt the lens and cause its extrusion through the pupil and corneal wound, hence greater liability to rupture of the zonular ligament and prolapse of the vitreous. This is debatable. Statistics do not prove it.

6. There is difficulty in delivering the lens through a small (and perhaps rigid) pupil and through the corneal section encumbered with iris. Moderate pressure will cause the sphincter of the iris to relax by the advancing lens, and if the operator's manipulations are deliberate and not too hasty the delivery of the cataract can be accomplished with ease.

7. The iris is bruised during the delivery of the lens causing subsequent iritis and synechiæ. This is not proved by statistics, and while convalescence may be delayed by iritis, subsequent vision is not impaired.

8. The iris frequently becomes caught in the corneal section and must be replaced. This is not a difficult procedure, and does not affect the result.

9. The toilet of the wound is difficult because cortical remnants remain behind the iris. It is probably true that thorough cleansing of the eye of cortical matter is more difficult, but the few small masses remaining do not get into the wound and cause irritation and delayed union, but are gradually absorbed.

10. Prolapse of the iris is a frequent complication and causes delayed union and necessity for another operation which is either painful or may require a general anesthetic for its abscission, results in anterior synechiæ or cystoid scar, and renders the eye liable to suppuration, iridocyclitis, glaucoma, and sympathetic ophthalmia.

Dr. Knapp calls iris prolapse the "bête noir" of simple extraction, and Gifford says "if it were not for prolapse of the iris, simple extraction would be employed."

Prolapse of the iris is usually traumatic in origin. The wound closes, and then some traumatism reopens the wound, causing a rapid escape of aqueous carrying the iris with it.

Small prolapses frequently require no treatment, and even the large ones often flatten down and cause no subsequent disturbance. Certain it is that with all the danger of prolapsed iris the relative proportion of suppuration, iridocyclitis, glaucoma, and sympathetic ophthalmia, is not so large as that resulting from other methods of operating.

By careful exclusion of unmanageable patients, by making the corneal section rather well into the cornea, by keeping the eye quiet by a simple occlusive bandage without exercising undue pressure on the eye, by avoiding excitement, by keeping the patient quiet and free from pain, if necessary by the use of morphine, and by careful attention to the bowels, to avoid straining at stool, the proportion of prolapse will probably be reduced to a minimum.

It may be objected that a corneal section means delayed union. Delayed union does not, however,

mean prolapse, as may be readily proven by statistics.

11. Patient must be unusually quiet to avoid prolapse.

12. Early inspection is necessary to discover prolapsed iris. The existence of prolapse may usually be diagnosed before the bandage is removed. The patient's statement of sudden pain with a gush of warm fluid from the eye is usually diagnostic. If such a history is not obtained, the eye may remain bandaged. It is my preference, however, to examine every eye at the end of twenty-four hours. I have yet to learn of a prolapse or a suppuration directly attributable to early inspection of the eye.

13. Astigmatism is higher after iris prolapse.

14. The pupil is not always round and movable. This is due to posterior synechiæ, the margins of the cut capsule becoming adherent to the iris. Careful performance of the capsulotomy in the periphery of the lens, together with the judicious use of atropine, will do much to avoid synechiæ.

15. Retroversion of the iris. This occurs very exceptionally after prolapse of the vitreous, and affects only the cosmetic appearance of the eye.

16. Secondary cataract is not so easily treated. With the pupil dilated with atropine there is usually ample room to perform discission. If the pupil is small from posterior synechiæ, a sufficient opening may still be easily made if discission is performed within two to six weeks after the cataract extraction, and before the capsule has become tough.

If now we consider the operation of simple extraction from the operator's view-point, it is my opinion that the "personal equation" enters largely into the method which an operator adopts. Good operators will probably select the operation which affords the most perfect result. Operators who are handicapped by some inability to perform some step well or to handle certain instruments skillfully, will naturally follow the method which does not expose their weakness. An operator will, therefore, select that method which gives him the best results according to his skill.

From the patient's standpoint the desiderata are: first and most important, integrity of the eye and sight; second, cosmetic result; and third, time. These, I believe, are best conserved by simple extraction.

To sum up, then, I quote Dr. Knapp's statement that "simple extraction is not only the best but also the safest operation for senile cataract and many other cataracts."

If now we compare the simple and combined methods of cataract extraction, the following objections to the method with iridectomy may be raised:

1. Iridectomy is an unnecessary mutilation and the burden of proof rests with those who employ it.

2. The cosmetic results are not pleasing.

3. Visual fields and acuity are impaired by a keyhole pupil.

4. It is a more difficult operation. It is simple extraction plus iridectomy.

5. Cutting the iris is frequently painful, causing the patient to squeeze the lids or to pull away, tearing out the iris or causing prolapse of the vitreous.

6. Iridectomy is often imperfectly performed and the pillars of the coloboma are not properly replaced.

7. Blood in the anterior chamber from the cut iris obscures the field of operation and may necessitate immediate lavage of the anterior chamber with its attendant danger of traumatism or infection, or may require postponement of extraction to another time. Blood in the anterior chamber may organize, causing thickened capsule with its consequent troubles.

8. Tags of capsule and particles of lens substance are more liable to get into the corneal wound and cause infection, delayed union, cystoid cicatrix, iridocyclitis, sympathetic ophthalmia, and glaucoma.

9. Prolapse of the vitreous is much more frequent than in simple extraction and is more dangerous. Retinal detachment and hemorrhage are liable to result from escape of vitreous. Impaired vision, if not actual loss of the eye, may follow.

10. Iritis is more common than in simple extraction and synechiæ frequently result. Iritis spells delayed convalescence.

11. More instruments are required, hence more danger of infection.

12. The operation is longer, therefore greater risk of infection is incurred.

13. An assistant is necessary whose skillfulness may not always be dependable.

These objections to the combined operation may be confirmed by the statistics of Dr. F. W. Ring (MEDICAL RECORD, February 23, 1895), who collated the results of 1,032 combined extractions and 1,123 simple extractions made by operators of recognized ability in America and Europe.

The comparative table reads as follows:

	Simple	Combined
Prolapse of vitreous	4.27%	7.23%
Average vision after vitreous prolapse	0.29	0.23
Incarceration or iris	4.00%	4.82%
Prolapse of iris	8.60%	None.
Iritis	11.82%	13.15%
Suppuration	1.30%	1.91%
Discission	33.04%	27.61%
Perfect success	90.82%	88.08%
Partial success	6.30%	7.45%
Failure	2.88%	4.47%
Average vision	0.48	0.34

These figures show that in spite of the dreaded iris prolapse, perfect success and average vision are greater in simple extraction, while iritis, prolapse of vitreous, suppuration and total failure are more common in the combined method.

To quote Dr. Knapp: "If we allow 10 per cent. for iridectomy as indicated by various unfavorable conditions; that iris-prolapse must be excised in another 10 per cent; and there are 10 per cent. of posterior synechiæ, there are still 70 per cent. of ideal recovery and the other 30 per cent. are much in the same condition as an equal number of combined extractions."

In conclusion, let me say that while both methods have their respective fields of usefulness, simple extraction is the best method of removing mature, senile cataract.

16 EAST FORTY-THIRD STREET.

THE HEPATIC FUNCTIONS, THEIR PATHOLOGY AND TREATMENT.

BY H. RICHARDSON, M.D.,

BALTIMORE, MD.

LECTURER ON PHYSIOLOGICAL CHEMISTRY AND ON NEUROLOGY AND PSYCHIATRY, UNIVERSITY OF MARYLAND; PATHOLOGIST TO THE MARYLAND TRAINING SCHOOL FOR FEEBLE-MINDED CHILDREN, LATE PATHOLOGIST TO MOUNT HOPE RETREAT.

THE importance of the proper functioning of the liver to the well being of the organism is apparent, it being the largest organ of the body; through it pass all the substances absorbed from the intestinal tract, whether nutritive or toxic, upon which it has to pass judgment, selecting, modifying, eliminating by the bile into the intestine, or storing them up within itself to be passed into the general circulation

according to the needs of the organism; it is a reservoir for the blood, upon which it acts as a depurator. The functions of the liver are in direct relation with the intestine, the pancreas, and the spleen; it has excretions and secretions which have a chemical activity of vital importance to the organism. It is impossible in the short space of this paper to go into the detail of the various hepatic functions and the far-reaching pathological effect of their insufficiency. For the blood, the liver acts as a reservoir, as a destroyer and as a manufacturer of erythrocytes, especially in fetal life; it is the storehouse for the iron; it controls the coagulability. The alimentary functions are glycogenic; it acts by its secretion, the bile, upon the fats in the intestine, storing them in its cells; it is probably the organ where sugar and fats are formed from proteids, and where fats are formed from carbohydrates and carbohydrates from fats; it is the organ which transforms the toxin into a nontoxin, arresting and eliminating them by the bile into the intestine; in fact the liver may be considered as a chemical laboratory in which a number of oxidative and hydrolytic processes are going on and as the depurator of the body. It is with the antitoxic function of the liver and the secretion and excretion of bile with which this paper is concerned.

Many of the functions of the liver are independent of life, that is to say, they occur in the liver when separated from the body, and in many cases the reactions can be produced by extracts from the glands. For example, if the extirpated liver be divided, and a part kept under aseptic conditions for several days, it will be found upon analysis that the amount of urea is very much greater in the latter than when the liver was fresh, showing that urea was formed after death in the liver cells (Ch. Richet). Chassevant showed that if the liver was heated to 100° C. it was inactive; that if the extract of liver was precipitated by alcohol the precipitate had the power of forming urea, and that this ferment, though present in man, dogs, and rabbits, was absent in birds, which do not excrete urea but uric acid. When ammonium carbonate and carbamate, amidoacids, xanthin, hypoxanthin, uric acid, leucin, and tyrosin, are fed to animals an excess of urea in proportion to the amount of substance taken is eliminated; Richet has been able to produce urea from many of these substances by means of the ferment extracted from the liver; all these bodies are more or less toxic. Any failure of the liver to transform them into urea must necessarily produce an autointoxication, they being much more toxic than urea, which, according to Bouchard, is forty times less toxic than ammonia, besides being a powerful diuretic. The formation of uric acid from ammonia has been demonstrated in the goose, but it is not safe to deduct that the same reaction takes place in mammals.

The salphoconjugation of the phenols is another function of the liver which is of great importance; the phenols are markedly toxic, but when combined as sulphates their toxicity is very slight. Carnot, Chassevant, and others have found ethereal sulphates in the bile, so that it is by the bile they are eliminated from the liver, where the combination takes place when not in too great quantity, and it is only the excess which appears in the urine.

The transformation of certain alkaloids by the liver is of great interest. Vergoogen found that on triturating hyoscyamine with frog's liver the alkaloid lost its mydriatic power, which was transmitted to the liver extract, but disappeared on heating to 70° C.

The depuratory rôle of the liver goes still further. The elimination of poisons by the bile has been established by Haidenhaim, Wertheimer, and other experimenters. The elimination of lead, copper, mercury, arsenic, etc., by the bile has been definitely demonstrated, the liver holding the metals as they come to it in the circulation and eliminating them in small quantities by the bile. Coloring matters are also eliminated by the bile—fuchsin, anilin red, indigo carmine, etc. Bilirubin, the normal coloring matter of the bile formed from hemoglobin, it being hemoglobin minus iron, is most decidedly toxic, producing many of the symptoms in jaundice; according to Roger, Carnot, Gilbert, Lereboullet, and others, when present in the proportion of 1 to 15,000 in the blood plasma it produces marked toxic effects.

Most of the toxins eliminated by the bile are retained for a certain time in the liver and eliminated in very small quantities so as to immunize the system, rendering their presence in the general circulation harmless. Potassium iodide and sodium salicylate are eliminated by the bile, but not so rapidly as by the urine. Many of the alkaloids (strychnine, curatine, caffeine, etc.) have been found in the bile after their administration, but the action of the oxidizing ferments of the liver usually converts them into unrecognizable substances.

Insoluble substances are arrested by the liver and absorbed by the cells, as shown by Carnot, and are either eliminated by the bile or are carried by the endothelial cells of the hepatic capillaries to the blood and thence to other organs. Its bacteriopexic as well as granulopexic power has been demonstrated. Gilbert, Lion, and Yersin showed that *B. tuberculosis*, when injected into a vein, accumulates in the hepatic spaces, remaining unchanged until the fourth day, when it begins to multiply; on the ninth day tubercles commence to form. The protective power of the liver against bacteria has been shown by Roger. Injection of anthrax into the aorta or peripheral vessels caused death in from 37 to 40 hours, but the animal survived if the injection was made into the portal system of a quantity of bacilli sixty-four times greater than would kill by the peripheral vessels. Lemaire is of opinion, supported by experiment, that the endothelial cells of the hepatic capillaries have greater phacocytic power than the leucocytes of the blood. According to Hanot and Gilbert, the liver has a cytopexic power, viz., embolic cancerous cells, arriving at the liver by way of the portal vein, are arrested by the hepatic capillaries at the periphery of the lobule, where they are either destroyed or give rise to secondary cancer of the liver.

The liver then acts as depurator to the system of soluble and insoluble substances, endogenous and exogenous toxins, it is also granulopexic, cytopexic, and bacteriopexic by virtue of the action of the hepatic cells, of oxydases and reductases, and by a special chemiotaxis of the endothelial cells of the hepatic capillaries, producing chemical changes, rendering the substances nontoxic and capable of elimination by the bile or other eliminators. Upon these functions of the liver depend the whole theory of autointoxication as an etiological factor in disease. Strictly speaking, experimental proof of autointoxication is wanting except in a very few instances, viz., when the toxin is found in the intestine and in the urine, and when injection of the isolated toxin produces the same symptoms in a healthy subject; but such a proof can be obtained only under almost impossible conditions of similarity and with toxins of very marked symptomatic effect.

There are but three ways by which the living cell can be injured, viz., starvation, intoxication, and traumatism; any two or all three may be combined in producing the cellular condition which gives rise to the clinical symptoms. To simulate autointoxication in the laboratory, the intoxication must be continuous, not intermittent or remittent, as in the hypodermic injections of toxins at certain intervals, between which the system has time to recuperate and eliminate; the poison must enter the system continuously, over long periods of time, gradually overcoming the immunization against it, varying in quantity and effect consequent on the varying conditions of environment. Autointoxication must be due to some lesion of some organ or loss or partial loss of some function, which in the laboratory experiment it is impossible to imitate, except by the excision of whole organs, as in the case of cachexia strumipriva, the result of ablation of the thyroid. In certain exogenous intoxications (alcohol, lead, arsenic, etc.) we have an approach to these conditions, employment or habit intoxications, which produce a very different clinical picture from acute poisoning with the same drugs. The facts taken advantage of in therapeutics, that small doses frequently repeated are more effective than one large one, and that each drug has two physiological actions, that following minute doses being the opposite to that of a large dose, applies to autointoxication; in the body autointoxication is due to small doses continuously given; in the laboratory the experiments are with large doses given at long intervals.

If we admit that the liver has antitoxic functions, we must also admit that if it ceases to functionate these toxins will enter the general circulation and produce pathological conditions. So evident does it seem that autointoxication is possible that the *onus probandi* as to its nonexistence must rest in this case on the negationists; the old harbor of refuge, "reflex action" from the abdominal nervous system can no longer be considered conclusive, for to have a reflex action there must be stimulation; if there is stimulation there must be a stimulant; if the stimulation is not physical it must be chemical, and if chemical it must be toxic if it gives pathological results.

The treatment of autointoxication is really the problem to be solved, few clinicians doubting that it is a potent factor in disease. In acute cases thorough flushing out of the alimentary tract with calomel and magnesium sulphate is usually sufficient, but in those cases of neurasthenia, nervous breakdown, nervous dyspepsia, etc., more is required in long, careful dietetic and medicinal treatment. Attention to the biliary secretion is of the utmost importance. The intimate association of the bile with the emotions has been accepted by the laity at least, the name melancholia, "black bile," having been given at a very early date to that form of insanity in which depression is the most evident mental symptom. The bile contains the coloring matters, bilirubin, etc., end products of hemoglobin disintegration; cholesterin, a substance which appears to be an end product of nerve metabolism, is held in solution by the bile salts, any diminution of the latter causing its precipitation and consequent formation of gallstones; mucus and the various end products of hepatic metabolism and the toxins arrested by the liver, either in their original form or chemically altered so as to render them soluble in the bile and inert in the intestine. The active principles of the bile are glycocholate and taurocholate of sodium, which hold the cholesterin and bilirubin in solution, preventing the formation of gallstones, as well as the chemical products of the liver; without their presence the bile ceases to flow, the liver becomes congested and insufficient, the organism suffers from starvation on account of the cessation of the nutritive functions of the liver, and also becomes intoxicated from the nonelimination and chemical conversion of the toxins. Nature is extremely conservative of the bile salts; after being eliminated into the intestine, where they materially assist in the absorption of fats, indirectly increasing peristalsis and inhibiting the growth of bacteria, they are resorbed from the intestine to be neutralized by the liver in the elimination of waste products. It is evident that in diseased conditions, after cleaning out the alimentary tract, the purgation of the liver and the stimulation of the functional activities of its cells is of importance. Nature's method—and we can never do better than imitate and assist her, is to increase the quantity of bile. The so-called cholagogues of the Pharmacopœia have been proven by numbers of physiologists not to increase the formation of bile, and the only cholagogue is Nature's, the bile salts, sodium glycocholate, and tauroglycocholate. The administration of sodium glycocholate mass, which contains taurocholate of sodium, by the mouth, it being absorbed from the intestine, increases the flow of bile, at the same time stimulating the liver cells. (Sodium glycocholate C P is not well borne by the stomach, producing nausea, burning, and painful diarrhea.)

The increased amount of bile salts dissolves, especially if given with high enemas or full doses of water containing sea salt in isotonic solution, the accumulated impurities in the liver, stimulating the liver cells according to Croftan, who uses them in nephritis, thus purifying the blood, enabling it to oxidize and removes the end products of metabolism from other organs. This is especially evident in the icteroid condition observed in cholemia; after the administration of sodium glycocholate mass for a few weeks the complexion clears up, and the yellow-brown spots disappear, leaving a normal, healthy complexion. Recently Gilbert and Lereboullet have called attention to the fact that certain symptoms, such as epistaxis, purpura, hematemesis, and hemoptysis, are often associated with the presence of traces of bilirubin in the plasma, and that under appropriate treatment by diet and stimulation of the biliary secretion improvement takes place.

The diet in hepatic disease, and especially in autointoxication, is of great importance. In the first place the quantity of food taken should be small; secondly, it should be easily digested, and must, therefore, as far as possible, correspond with the patient's tastes or the psychic stomach juice will not secrete; thirdly, it must contain no substance which is itself toxic or which will produce a toxic substance during metabolism; fourthly, it should be a bad culture medium or contain some inhibiting substance for the growth of bacteria

Rest is the best medicine for any deranged physiological function, and starvation is rest for the liver. The food should therefore be reduced to the minimum quantity required for physiological needs, about 3 ounces of proteid per diem; no soup should be allowed, as it contains the extractives and but little nutriment, and the former throw extra work both upon the liver and upon the kidney; carbohydrates in any form, well cooked, preferably using lactose, instead of cane sugar, should be the principal diet.

So far intestinal antiseptics have proved inefficient. In very acute diarrhea I have had good results with the administration of iodoform in full

doses as long as the diarrhea lasted. I give it with calomel in typhoid fever, but it has to be carefully watched, owing to its toxic properties if absorbed; if the bowels are kept moving freely very little is absorbed. Aristol is not so objectionable, nor is it so efficient. Salicylic acid, salol, bismuth, and the whole gamut of the drugs of the Pharmacopœia have been tried and found wanting. Probably the use of metallic colloids, owing to their ferment-like action, may be found valuable when better understood; brewers' yeast is decidedly effective; it can be administered as cheese or as weissbeer. The lactic acid bacillus has also a powerful antiseptic action in the intestine; it is for this reason that milk diet is antiseptic, the lactose not being a good culture medium for bacteria; for the same reason lactose as a sugar is a good antiseptic, reducing the amount of ethereal sulphates in the urine.

Chemical antidotes have not been found for the organic toxins, which are an ever-present menace to health. Our greatest hopes rest upon the action of oxidizing ferments, and as the oxydases, which introduced into the intestinal tract or into the circulation well oxidize the toxins, thus rendering them inert. Sieber has shown that the vegetable oxydases will destroy the diphtheria and tetanus toxins, both *in vivo* and *in vitro*.

Autogenous and exogenous intoxications are factors in producing the symptom complex of nearly all diseases, and are to be combated by stimulation and purgation of the liver, which can be brought about by the administration of sodium glycocholate mass and a careful and abstemious diet.

A CASE OF VERY LARGE DILATATION OF THE CECUM.

By THOMAS W. HARVEY, M.D.

ORANGE, N. J.

Mr. D., married, U. S., merchant, age 62, with an alcoholic history, was taken sick on March 6, 1907. His previous health had been good, except that he had recently fallen on the ice and hurt his back and right side, for which he received treatment by manipulation. A recent examination of the urine showed a "trace of albumin and narrow hyaline casts."

On March 6 he had a catarrhal cold; on March 8, Dr. English, his attending physician, discovered signs of pneumonia in the upper lobe of the right lung. Temperature 102.3°, pulse 85, respiration 30.

On March 10, temperature 103°, pulse 92, respiration 25. He had passed large quantities of gas from his bowels and had had several fluid stools. On this day his abdomen commenced to swell.

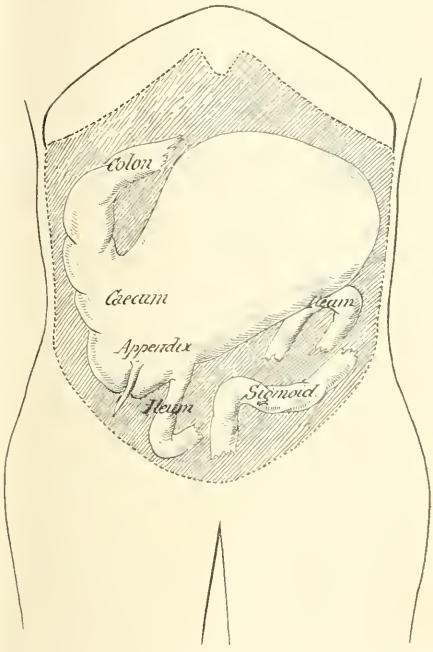
His temperature varied between 102° and 104° until March 16; he had cough, expectoration of brownish sputum, pulse varying from 85 to 100. On March 16 his temperature dropped to 100°, and remained between 99.4° and 100° until March 22. His pneumonia symptoms gradually disappeared, but his abdominal distention continued.

On March 23 I examined him with Dr. English. There were râles present in his lungs, and it appeared that the pneumonia was in the period of resolution. His abdomen was distended, tense, and tympanitic everywhere. It was very sensitive to pressure over the left side, and he complained of severe pain in his epigastrium. Temperature 102°, pulse 108, and feeble. He presented the appearance of a man with peritonitis. There was constipation, but no obstruction; fecal matter came away with enemata, and through movements were obtained by cathartics. He would pass flatus, but evidently could not empty his intestines. He had vomiting, but it was not stercoraceous.

His temperature dropped on the next day and remained low, about 100° in the rectum, until just before his death, on March 30, 1907. His pulse became more rapid and feeble as his heart grew weaker, and he developed a pulmonary edema which was soon fatal.

The question of laparotomy was raised, but an artificial anus seemed the only thing that might be indicated. It is doubtful from the autopsy if any operative measure could have helped him.

Autopsy.—Abdomen greatly distended and tympanitic. When the abdomen was incised gas escaped from the abdominal cavity. Inspection showed a large, distended sac in the abdomen full of gas; this was adherent to the diaphragm and the abdominal wall on the left side, and to a coil of small intes-



tine at the lower left hand edge; this sac extended from side to side, and from the diaphragm to the rim of the pelvis; adhesive peritonitis was present everywhere. At first sight this sac looked like a largely dilated stomach, but the fact that the omentum and the transverse colon could not be found in their usual relation negatived this idea. A small perforation was found near the attachment to the diaphragm; we were in doubt as to whether this perforation was the result of our manipulation, or had existed before death; certainly manipulation enlarged it.

The sac when opened was found to contain gas and a small amount of fecal matter. The adhesions having been separated, the stomach and omentum were found behind the sack, also the transverse and descending colon which were contracted and empty. A coil of small intestine was firmly adherent to the lower border of this sac, and a small amount of pus was found between the coils at this point, but there

was no perforation. Further examination of the sac showed that on the right side the ileum emptied into it with a normally formed ileocecal valve, that the appendix, which was somewhat enlarged at the base, was, relatively to the ileocecal valve, in its normal position, and that the ascending colon opened out from the upper right hand corner of the sac without obstruction. It seemed like a huge diverticulum or lateral dilatation of the cecum. The wall was similar to the normal intestinal wall, only much thinned. The liver was cirrhotic and the kidneys enlarged, and the right showed sclerotic changes.

The large intestine beyond the hepatic flexure was empty and contracted, but there was no evidence at any point of obstruction. This was due to the persistent and successful use of high enemata during the last few days of life.

The small intestine was normal, and showed no evidence of abnormal distention. The tympanites was due to the great dilatation of the cecum and to a moderate amount of free gas in the abdominal cavity.

Cases of dilatation of the intestine are frequent in medical literature. Many are due to definite obstruction, such as fecal impaction, growths, strictures, or twists of the bowels, intussusception, adhesions, bands, etc. Others are really dilated diverticuli, but these are usually small, and Meckel, after whom these have been named, insisted that they are found only in the small intestine. Then there have been many cases of so-called idiopathic dilatation, usually of the large intestine, reported by capable observers, in which a definite obstruction has not been found beyond the dilatation. Some of these cases have been very acute. These dilatations have been usually found in the descending colon or the sigmoid. In this case there was a partial dilatation of the cecum. In Allbutt's "System of Medicine" it is stated that these partial dilatations of the intestine are similar to the dilatations of the stomach that occur without pyloric stenosis.

It has been suggested that a partial dilatation, such as this, may have been due to paralysis of the nerves supplying this part of the gut. If this is so, then it will be of interest to inquire as to the causative relation of the accident that preceded his illness.

In his inaugural dissertation at Göttingen, Ernest Cordua describes a monstrous blind pouch in the large intestine which was given off from the ascending colon. The swelling of the abdomen appeared early in life, and the patient, whose death occurred at twenty-two years of age, had been under observation for thirteen years. At the autopsy two large coils of the large intestine were observed, filling the abdomen. These were filled with gas and feces. On incision it was found that one of these coils was a blind pouch communicating with the colon at the hepatic flexure. It was 1.2 meters in length. Cases of doubling of the large intestine have been described, and Cordua's case has been regarded as an abortive attempt at a doubling of the colon.

Other cases are described as "saeculations of the colon," in which there is a bulging of the inner coat of the bowel through the muscular coat due to some defect in the muscular layer.

Dilatation due to obstruction, in my experience, has always been of the whole diameter of the gut, and in the case that I have seen, the ileocecal valve has not offered any resistance to the dilatation extending to the small intestine. In this case the ileocecal valve was competent to prevent any reflux from the cecum, and there seems to have been a dilatation affecting only one side of the cecum.

Treatment of Sciatica.—Dr. E. S. McKee of Cincinnati advises the following: First, a calomel purge, then salts; in constitutional disease as soon as possible introduce treatment for the cause. One should use caution with morphine, in rheumatic cases salicylate preparations, in syphilis iodides, in gout colchium and saline mineral waters. Hypodermic injection of sterilized air. Naturally, care must be taken that the hypodermic syringe needle be not run into a blood-vessel, which might easily occur. Gentle massage should follow this procedure till the air is all absorbed. The rest cure is in some cases very successful, especially in those whose means of livelihood has been an active one. Massage along the nerve, though quite painful, often breaks up adhesions, which are the cause of the disease in many instances. It is a rule, however, that in true neuritis massage is not followed by good results. Massage, and especially vibrations, are of especial worth in chronic cases with beginning atrophy. Hydrotherapy systematically used deserves due consideration. The wet pack over night diminishes the pain remarkably, as well as having a favorable influence on the neurotic process. The next morning the leg is unpacked, washed with warm water, and massaged. Ten or twelve of these applications are usually sufficient. In subacute cases the half steam bath is of service. Patient sits in a steam container which reaches only above the hips. This half-steam bath does not weaken the patient, and allows of a higher temperature. 44° C. can be endured for 10 to 15 minutes without discomfort. Afterwards the patient is put in a bath of 35° C. for eight minutes and douches the diseased hips with water at 40° to 44° C. This procedure can also be combined with swimming baths, and very often the drinking of large quantities of water is advisable. Electrotherapy, the galvanic current applied directly to the nerves for from 4 to 8 minutes, highest 3 to 5 milliamperes. Also the interrupted galvanic current stimulates the muscles in a mild way, holds the tissues in a good condition, and prevents atrophy. The static douche, with positive pole on the painful part, is followed by good results. The apparent anodyne action of faradism in sciatica is due to its alterant action on the muscular tissue, and through that on the circulation. The current should not be increased to painfulness. Surgical treatment: In long standing cases one is often led to make an exploratory incision, lay the nerve bare, and separate some adhesions. In bloody nerve stretching, we find good and bad experiences. This operation is directly contraindicated when neuritis is present, as in these cases myelitis not infrequently follows. There is also a so-called bloodless nerve stretching, wherein the patient is under ether, the thigh is forcibly flexed on the hip joint with the leg extended at the knee, which position is maintained for some minutes. The cure is easier when the patient is not too old and does not suffer from other diseases. The principal thing in the treatment consists in the careful observation of the patient, so that nothing is overlooked. The physician shall at once in the beginning commence with a systematic cure, and, if it does not go forward, seek for his failure, for failure lies somewhere certainly. Exact diagnosis of the condition of the patient is the first and last means of treatment.—*Blätter für klinische Hydrotherapie.*

Treatment of Erysipelas.—As an internal remedy quinine in 4 to 8-grain doses, according to the temperature, may be given three or four times daily, and the following may be used as a local application: Perchloride of mercury 1 grain, lanolin and vaselin, of each, half an ounce.—*The Hospital.*

Acute Appendicitis.—Ochsner says that all practitioners of medicine and surgery, as well as the general public, should be impressed with the importance of prohibiting the use of cathartics and food by mouth, as well as the use of large enemata, in patients suffering from acute appendicitis.—*Journal of the Michigan State Medical Association.*

HEART CLOT IN PNEUMONIA.

In the older text-books the occurrence of cardiac thrombosis was recognized as one of the dangers in pneumonia, and indeed as a not infrequent cause of death in this disease. At the present time, however, largely owing to the teaching—or rather, we may say, the silence—of pathologists regarding the phenomenon, there is little insistence upon this complication; indeed it is almost ignored by the majority of writers. In an article in the current issue of the *American Journal of the Medical Sciences*, Beverley Robinson notes this fact and quotes a number of personal communications from some of the leading pathologists in this and other cities, showing that there is a general disbelief among them in the frequency or the importance of ante-mortem clot in pneumonia. Clinicians, on the other hand, are still for the most part of the opinion that cardiac thrombosis constitutes a very real danger in pneumonia, and Robinson is himself convinced that this is true. He holds that this complication may be overlooked by reason of the presence of the alarming symptoms due to the extensive pulmonary lesions and the profound toxemia, but the sudden occurrence of grave cardiac symptoms and the rapidly fatal termination of the disease point to it unmistakably. The heart clot, he says, may occur during the acute stage of pneumonia when other symptoms are grave; it may occur just after the crisis, when everything appears hopeful; and it may occur during convalescence, when all danger is seemingly passed. Pulmonary thrombosis also is usually present in connection with the heart clot. In private practice it is often impossible to confirm the assumed presence of heart clot by post-mortem examination; and even when an autopsy is made, the pathologist finds structural changes in the heart muscle to which he attributes the fatal termination, the heart clot being regarded as merely a result of these changes and of minor importance. But Robinson argues that these myocardial changes are probably no greater than in other cases in which death is obviously due to some other cause, and that they are even less pronounced than in some other acute infections, typhoid fever for instance, in which death from the heart is less frequent than in pneumonia.

The importance of this insistence upon the not infrequent occurrence of cardiac thrombosis in pneumonia is in relation to the therapy of the disease. If heart clot is a common, or even an occasional, cause of death in pneumonia, the indication is clearly to reduce the coagulability of the blood. Todd (*New York Medical Journal*, March 20, 1905) recommends six to eight ounces every two hours of a solution of 2½ grains of sodium chloride and 1 grain of potassium bicarbonate to the ounce. The addition of lemon juice makes the mixture more palatable and probably also increases its efficacy. Lemonade itself is useful, and Robinson recommends it, not only as an agreeable refrigerant drink, but also because of its action in diminishing the coagulability of the blood whenever there is reason to dread heart clot. The remedy which he especially urges is, however, ammonium carbonate. In former days this constituted a routine part of the treatment of pneumonia, but it was given chiefly for its stimulant effect. Robinson does not give it for that purpose, regarding alcohol as preferable, but he does look upon it as a valuable prophylactic remedy in relation to heart clot. Quoting from a former communication, he says that keeping the blood fluid is, in the grave forms of pneumonia and where there is extensive pulmonary consolidation, a very important matter, and he adds that he has seen many patients in whom, before death and at the autopsy, he is convinced that heart clot avoided would possibly or probably have meant a life saved.

The evidence of the value of specific medication in pneumonia is too strong to be ignored, and the first duty of the clinician is to attack the disease—to jugulate it if possible, to restrain the activity of the pneumococcus, and to antidote or dilute its toxins. But whatever method may be adopted with this end in view—sweating combined with diuretics and saline infusions, open air, creosote carbonate, the salicylates, etc.—the special dangers of the disease are always to be borne in mind, and one of these, perhaps the most formidable in its suddenness and fatality, is heart clot. To guard against this, as Robinson says, carbonate of ammonium is one of the most efficacious of the remedies at our command.

THE MEDICAL INSPECTION OF SCHOOL CHILDREN.

In all parts of the civilized world the public conscience is awakening in regard to the neglect of the health of the young. Perhaps, however, a more apt mode of expressing this change of front would be to say that the public has become alive to the fact that a healthy population is necessary to the physical, mental, moral, and material welfare of a nation. The latest country to recognize in a practical manner that the good health of her school children is a national asset of great value has been Great Britain. It goes without saying that no country has such good cause to care for the health of her rising generation. The population of Great Britain is now mainly urban, and it is obvious that city life does not tend to preserve the health of the young. Furthermore, the birth rate of Great Britain is steadily declining, so that she has need to keep the fewer children born in good health, not to mention that it is incumbent upon her to rear adults who will be able to produce a healthy stock. The contention that those countries in which the inhabitants live chiefly in towns must use every effort to bring up children in as hygienic conditions as possible is one which requires little insisting upon. It is, in short, a case of national preservation, and the country which can raise the healthiest citizens in body

and mind, in the long run must be the most successful.

Of course, medical inspection of schools is an important factor tending in this direction. Every country in which it has had a fair trial on more or less systematic lines has reaped great benefit from its introduction. Statistics show that the adoption of systematized medical inspection of schools is followed by a considerable decrease in infectious diseases. European countries, especially Switzerland and Sweden, have amply demonstrated this fact. Great Britain is, curiously, behind all nations of the civilized world as regards medical inspection of schools. Even Russia, with more than 90 per cent. of her rural population unable to read or write, has medical inspection of schools, and Chili, Argentina, Servia, and Bulgaria have all a fairly elaborate and effective system of school inspection.

At the International Congress of School Hygiene held recently in London, the subject in which the greatest interest was taken, and, to speak truly, the only one which was keenly discussed, was that of medical inspection of schools. The discussion was carried on by distinguished delegates from all parts of the world, and for this reason was especially valuable, in that the interchange of views threw fresh light on the matter. Although thus far Great Britain has been lethargic, it seems now that she intends to move with decision, albeit with discretion. A bill for the medical inspection of schools in Great Britain has passed already the House of Commons, and will undoubtedly become law during this session, that is to say, before the end of this year. Hand in hand with inspection will come into force in the elementary schools of Great Britain the teaching of hygiene. Sir John Byers, in an address delivered before the Congress of School Hygiene, sketched a scheme of such teaching, which will probably be closely followed by the framers of the bill. He said: "Children while at school should be taught both by example and precept the simplest rules of how to live, the necessity for fresh air, and for pure water, and for healthy homes, and the relative nutritive value of various kinds of foods which are ordinarily used. They should be instructed in the simple and ordinary laws of health and temperance, and in the importance of such matters of personal hygiene as cleanliness, the care of the skin and of the mouth (not more than 3 per cent. of all children of school age in England have sound teeth), how to deal with sudden emergencies, and how much can be done to prevent the onset and spread of infectious disease."

Great Britain will indeed, to a great extent, follow the lead of New York City in her scheme for the care of school children. This advance in school hygiene will be watched with great interest in this country, for, as pointed out above, no country presents so favorable a field for an experiment of this nature as does Great Britain.

TREATMENT OF RACEMOSE ARTERIAL ANGIOMA.

This form of neoplasm occurs more frequently in the arteries of the head than elsewhere, and is characterized by a tumor mass, consisting of newly-formed, dilated, convoluted, thickened, and pulsating arteries. Microscopically, the media and intima, both of the newly formed and already existing vessels, are found to be thickened by reason of newly formed connective and elastic tissue. The clinical features are usually marked; at the periphery the dilated arteries are visible and can be distinctly felt, often feeling like a bundle of earthworms. The tumors pulsate and the skin over them is thick or thin, with a light blue, or even dark blue color shining through it. They rarely give rise to difficulty in diagnosis, arteriovenous aneurysm and pulsating sarcomata being excluded by the presence of separate elastic tubes filled with blood. While these angioma are, as a rule, not accompanied by any subjective symptoms, their removal is indicated on account of the disfigurement they cause, their tendency to enlarge, especially during pregnancy, and because they are easily injured by combing or scratching, when they give rise to extensive hemorrhage.

The different methods of treatment of these growths have been discussed by Siegmund, Heyne, Krause, and Körte, and all agree that those methods which limit the blood supply, such as long-continued pressure at intervals on the afferent vessels, ligation of the afferent vessels, and ligature of the vessels of the neck do not produce permanent results, as the tumor also receives some blood by way of the bones, and a collateral circulation is soon established. Another method consists in an attempt to bring about obstruction of the blood-vessels by electropuncture, or by the injection of ferric chloride or alcohol, all of which produce an inflammatory reaction in the connective tissue, which in turn may produce sufficient pressure on the vessels to close them. This may be tried when the growth is too large to be extirpated or when the patient refuses operation, but recurrences may take place, and the treatment is long and tedious. The third group of methods aims at the direct destruction and removal of the diseased vessels. If this is attempted by actual cautery or acids, fatal hemorrhage may follow the removal of the sloughs. The only and most effective mode of treatment is dissection with the knife.

Control of the hemorrhage is the main difficulty encountered during extirpation, and various methods have been devised to diminish the amount of bleeding. These are discussed in detail by W. Körte in the *Deutsche medizinische Wochenschrift* for August 29, 1907. He found that an elastic head bandage was of little avail in most cases, while previous ligation of the main stem which supplies the tumor greatly diminishes the bleeding; if it is an angioma of the head the external carotid is tied. Of course, this does not empty the tumor entirely as a collateral circulation sets in, and as some of its content is supplied through the skull. In addition, he passes a mattress suture through the skin around the entire tumor, about two centimeters from its base; the growth is then extirpated within this suture, when the latter is removed and the bleeding vessels are ligated, the defect being closed by bringing the edges of the wound together. If the growth is very large the skin edges cannot be brought together and the skin over the tumor must be preserved. After ligating the main trunk as before, the mattress suture is not passed all around the tumor, but in horseshoe-shaped fashion, and

digital compression is made at the point (pedicle of the future skin flap) where the mattress suture has been omitted. An incision is then made down to the periosteum, just inside the suture line, when skin and tumor are rapidly dissected up together, the bleeding from the bone being easily controlled by gauze and pressure. The angioma can then be slowly dissected from the skin with practically no bleeding, while, if the skin were first dissected from the tumor before the latter was raised from the periosteum, the bleeding would be more profuse. The mattress suture is then removed and the vessels tied as before, and the skin flap is sutured in place. Körte usually also extirpates the afferent vessels as well, but thinks the procedure unnecessary, as they get smaller spontaneously after removal of the main tumor. Extensive racemose angioma on the extremities offers greater difficulties, as the tying of the large number of vessels which require this may give rise to gangrene, so that amputation must be considered in the treatment of such tumors.

Prognosis of Acute Poliomyelitis.

Until not so very long ago it was the general belief that a patient rarely died from infantile paralysis, and even to-day we find the opinion expressed in most text-books that acute anterior poliomyelitis is accompanied by little if any danger to life. The first one to oppose this view was Medin, who, in 1890, reported an epidemic with several deaths. I. Wickman, writing in the *Zeitschrift für klinische Medizin*, No. 63, 1907, agrees with Medin, and bases his opinion upon more than one thousand cases which occurred during an epidemic in Sweden. Of 1,025 patients, 868 developed a paralysis, while the 157 nonparalytic cases were considered abortive forms of the disease; in all 159 died, 14 after the second week of the disease of some intercurrent trouble, leaving 145 who died before the end of the second week, a mortality of 12.2 per cent. When we consider that many of the abortive cases in which recovery took place were not reported, this figure seems too high; on the other hand, if, as is usual in statistics of this kind, those cases only were considered in which paralysis developed, the figure would rise to 16.7 per cent. It can thus readily be seen that acute poliomyelitis is not a benign disease. The age of the patient also plays some part in the prognosis. Here again the findings during this epidemic were not in harmony with the general opinion that the older the child the better the prognosis. Wickman found that the morbidity diminished as the mortality rose, and that the older the patient the greater the mortality. He gives a table showing the death rate at each age, and then sums up by stating that in children under twelve the death rate averaged 12.2 per cent., while between the ages of twelve and thirty-two it averaged 27.9 per cent. Cases above thirty-two were too few in number to be included in the statistics. These figures show that the prognosis was better in young children than in older ones and adults; more died on the fourth day of the disease than on any other, the deaths on subsequent days diminishing rapidly in number, so that the prognosis as to life was good after the first week of the disease. As regards paralysis, Wickman believes there are many abortive cases without paralysis, and that while many cases of paralysis do not recover absolutely, a great many more recover completely than is generally believed to be the case. Most of Wickman's conclusions are contrary to the views usually held, but are based on a study of 1,025 cases, and are therefore worthy of consideration. There is hardly a disease in which the physician is so often subject to unjust criticism, and a knowledge of the prognosis is important, so that the relatives of the patient can be told the possibilities as to life and permanent recovery.

The Relation of Fat to Caisson Disease.

It has been stated that tunnel workers of spare build are much less liable to suffer from caisson disease than those inclined to the formation of fat, but hitherto no explanation of this difference in susceptibility has been offered. In a paper read some time ago before the Royal Society (*The Lancet*, September 7, 1907), Dr. Horace M. Vernon described some interesting experiments which offer a possible reason for this difference and also suggest an explanation of the mode of occurrence of the disease. He found that fats absorb air very readily, dissolving five times as much nitrogen as an equal volume of water or of the blood plasma, and he ventures the opinion that the special tendency of the fat-containing tissues (such as subcutaneous tissues, spinal cord, and peripheral nerves) of caisson workers and divers to suffer injury from the liberation of gas bubbles after rapid decompression is dependent on this great solubility. This special liability of adipose tissue to injury on rapid decompression is perhaps a resultant of two factors —its greater solvent power and relatively limited blood supply. These factors would reinforce one another, since more gas would be dissolved and its removal would be less easy than in other tissues. The rate of flow of the blood supply is also a factor. Hill and Greenwood (Proceedings of the Royal Society, Vol. LXXIX., 1907) found that on exposing themselves to a pressure of from 30 to 45 pounds their urine became saturated with the theoretical amount of nitrogen in from 10 to 15 minutes. This quicker saturation must be due to the blood flow through the kidney being much more rapid than that through the spinal cord, and very much more rapid than that through adipose tissues. But even, Vernon says, if it were as rapid through fat-containing tissues as through the kidney, the fats, in virtue of their greater solvent power, would take longer to become fully saturated than the fluids of non-fatty tissues.

A Rare Affection of the Gluteus Maximus Muscle.

In a recent issue of *Russkii Vratch*, M. M. Kouznetzoff describes a rare condition of the gluteus maximus muscle, in consequence of which the patient, by a voluntary contraction of the muscle, is able to slip its anterior fibers over the trochanter major, producing a crepitus and an audible click. The condition may easily be mistaken for another affection, namely, habitual voluntary dislocation of the hip. The author quotes the two reported cases of Ferraton and Baver *in extenso* and adds two cases of his own. Both of these were in soldiers, and the peculiar condition interfered with their work, causing pain and disability. The relations of the great trochanter to the Roser-Nelaton line and to Bryant's triangle were normal; all motions in the hip joint were normal and free; the click could be felt to be superficial when the hand was placed over the trochanter and the patient contracted the muscle;

at times the fibers of the muscle and its tendon could be felt gliding over the trochanter. Thus habitual dislocation of the hip was excluded. The cause of the condition is probably to be found in changes in the tendon of the muscle and abnormal mobility of its insertion.

News of the Week.

Wholesale Vaccination in Porto Rico.—Shortly after the occupation of Porto Rico by the American troops, a crusade against smallpox, endemic in the Island, was undertaken by the Army surgeons. Every inhabitant who could not show a good scar was vaccinated, with the result that there has not been a death from the disease reported since 1900. Recently, however, a number of cases of varioloid have occurred, and the authorities have decided upon another general vaccination. Vaccine sufficient for 600,000 inoculations has been ordered and the work of protection will be begun in the Guayama district, where the disease chiefly prevails.

Typhoid Fever at the Trenton State Hospital.—Between April 8 and August 23 there were 80 cases of typhoid, 15 fatal, in the New Jersey State Hospital at Trenton. Among those attacked were 23 employees and other residents in dwellings on the hospital premises. In a report to the State Board of Health by Dr. Henry Mitchell, Secretary, of an investigation undertaken to determine the cause of the epidemic, it is stated that investigations concerning the food supply, including milk and water, were negative, and the conclusion was reached that the disease was transmitted directly from patient to patient and through the agency of utensils and food infected within the building. This conclusion is justified for the following reasons: (1) The disease first appeared in the west wing of the main building and spread to other inmates in this wing and of other portions of the main building, but not a single case occurred in the annex, indicating that the infection was not conveyed by milk or water, for the supply of both of these articles was from the same sources for both buildings. (2) The spoons, forks, cups, etc., used in the dining rooms were washed by the insane inmates, without boiling, and, in the course of the epidemic, every utensil in the building probably became infected, thereby exposing the food which entered the building to infection as soon as it was received. (3) The filthy habits of many of the insane inmates of the hospital probably caused infected discharges to be generally distributed in the bath room, upon the furniture, doorknobs, and other surfaces touched by the hands of the infected persons. (4) Inquiry has shown that communication between the infected kitchens of the main building and the dwellings of employees, where cases of typhoid fever occurred, was frequent.

Typhoid Fever at Gouverneur Hospital.—Nine of the nurses and attendants at Gouverneur Hospital in this city recently came down with typhoid fever. They all ate at the same table, and the infection is thought to have been conveyed by some article of diet, probably a salad. All of the patients have been doing well and are expected to recover.

Tuberculosis in Iowa.—The Iowa Society for the Study and Prevention of Tuberculosis has discovered that tuberculosis is far more prevalent in the dairy district than in southern Iowa. This is held to support the theory that contact with dairy cows is a fecund source of tuberculosis in man. The Society will report its findings to the legislature next session and solicit an appropriation for stamping out tuberculosis in the dairy herds of the State. The Society has made claim to the sum of $5,000 appropriated by the legislature last spring for the purpose of compiling statistics and securing information regarding the progress of tuberculosis, the money to be expended under the direction of the State Board of Control. The Society desires to use part of the money to pay the expenses of their lecturer in the dissemination of information regarding the treatment and prevention of consumption. The Board of Control, it is said, wishes to use the money to pay for a new investigation of tuberculosis, and holds that that was the intent of the legislature in making the appropriation.

Insanity in Great Britain.—According to the annual report of the British Lunacy Commissioners, insanity is increasing to a considerable extent in that country. At the beginning of this year one out of every 282 persons in England and Wales was reported to be insane, whereas ten years ago the ratio of insane persons was only one to 314. From 1869 to 1906 the population of England and Wales increased 55½ per cent., while the insane increased 133 per cent. A significant fact brought to light by the report is the spread of senile dementia, which alone accounted for over 38 per cent. of last year's fresh lunacy cases. In this connection it is suggested that modern medical science is doing more for the body than the mind, so that the former is kept alive beyond the time at which the latter succumbs to the increased demands of the present mode of life.

Finger Prints in Banking.—The finger-print method of identification has been extended to commercial uses by the Postal Savings Bank of the Philippines at Manila. This bank has recently issued a series of stamp deposit cards on which are spaces for stamps of different values to be affixed. When the depositor has stamps to the value of one peso on the card it is exchanged at the bank for a deposit book showing the amount to his credit. Opposite the lines for the owner's signature and address is a square ruled off for the reception of his thumb print, so that, even if illiterate, depositors may readily be identified.

Milk Pasteurization.—The fifteenth season of the Nathan Straus distribution of pasteurized milk ended on September 16 with the closing of the booths in the parks and on the recreation piers. From the seventeen stations maintained by Mr. Straus, 2,917,330 bottles and 1,222,048 glasses of milk were sold or given away. Six of the depots will be kept open during the fall and winter as follows: 151 Avenue C, 47 Monroe street, 441 West Thirty-third street, 329 East Fifty-ninth street, 303 East 111th street, 38 Macdougal street. The new five-story pasteurizing plant in course of erection by Mr. Straus at 348-350 East Thirty-second street will be in operation by next spring. At the International Pure Milk Congress held in Brussels last week, the use of raw milk for infant feeding was officially deprecated and pasteurization was advocated.

Honors for American Medical Men.—The Mary Kingsley Medal, institute' by the Liverpool School for the Study of Tropical Diseases to commemorate Miss Mary Kingsley, the African traveler, has been awarded, among others, to the following: Dr. Charles Finlay of Havana and Col. W. C. Gorgas, U. S. A., Chief Sanitary Officer of the Panama Canal Zone, for their work in connection with the transmission and prevention of yellow fever, and Dr. Theobald Smith for his investigations on Texas cattle fever.

An Operation on King Alfonso.—The King of Spain recently submitted to an operation for the removal of adenoids from the nasopharynx. The removal was accomplished satisfactorily by Dr. Moure of Bordeaux, assisted by Drs. Alabern and Castaneda, and the operation was witnessed, for reasons of State, by Premier Maura and the Duke of Sotomayor, the Grand Chamberlain.

An Explosive Poultice.—A man in Albany recently applied a gunpowder poultice to reduce an inflammatory swelling of his arm, and when a friend struck a match to light his cigar the head flew off and ignited the poultice. The result was a degree of counterirritation rather in excess of the therapeutic indications.

A Crusade Against Feminine Cigarette Smokers.—A Chicago lady has come to New York to inaugurate a crusade against cigarette smokers of her own sex, and has begun by asking the members of the Colony Club, the new woman's club in this city, to sign a pledge to abstain from all intoxicating liquors as a beverage and from the use of tobacco in any form.

To Build a Hospital at Algonquin.—Preliminary arrangements have been made to begin the construction of a permanent group of buildings for the housing of the Chicago Tribune's Summer Hospital at Algonquin. Recently the hospital medical staff, with Superintendent E. P. Bicknell, of the Chicago Bureau of Charities, went over the ground and selected what, in their opinion, are the two best sites for the erection of a permanent plant. The hospital is to be built on plans which contemplate the erection of a series of buildings, which, when completed, will represent the highest type of modern sanitary hospital construction. In general, the hospital will consist of a group of cottage-like structures, each a complete building in itself, and all connected by a covered colonnade.

Chicago Hospitals Assessed.—Assessments have been announced against hospitals in Chicago amounting to more than two million dollars, the tax on which, it is said, will approximate $27,000. This assessment is the result of a decision recently arrived at that hospitals shall come within the scope of the taxation law.

Indiana University School of Medicine.—The Indiana University and the State College of Physicians and Surgeons, Indianapolis, on account of affiliation, have dropped these names, and that of the Indiana University School of Medicine has been substituted. The Board of Trustees of the State University is to have full control of the medical college. There is to be no change in the course of instruction, nor in the make-up of the faculty. The first two years of work are to be given at the State University, Bloomington, and the last two at Indianapolis.

A New Medical School in Denver.—The Westminster University, an institution under the control of the Presbyterian Church in Colorado, has recently established a Medical Department which will be located in Denver. The University had no charter for a medical school, but has taken in the Homeopathic College, a chartered school, and will add courses in regular medicine and in eclectic medicine, selecting its faculty from members of the three schools of practice.

New Building for Tulane.—It is proposed to erect a new building for the Medical Department of Tulane University, New Orleans. The building will be on the University campus, at a cost of $150,000.

College of Medicine, Syracuse University.—The following changes in the faculty of the college are announced: Dr. Frank P. Knowlton, at present associate professor of physiology, has been advanced to the head of the department of physiology. Dr. Harold Dickenson, Sr., at present an Associate in Anatomy at the Wistar Institute of Anatomy, Philadelphia, has been elected to the chair of Anatomy, and as director of the Anatomical Laboratory at Syracuse University, to take the place formerly held by Dr. George M. Price. Dr. Gustave M. Meyer, for four years assistant to the chair of Physiological Chemistry at Columbia University, New York, has been elected to the chair of Physiological Chemistry in the Medical College of Syracuse University. Dr. Meyer succeeds Dr. George A. Hanford, resigned.

Association of Burlington R. R. Surgeons.—At a meeting held in Denver on August 29, a society of railway surgeons was formed with the title "Chicago, Burlington and Quincy Association of Railway Surgeons." The election of officers resulted in the choice of the following: *President,* Dr. T. P. Livingston, Plattsmouth, Neb.; *Vice-President,* Dr. B. B. Davis, Omaha; *Treasurer,* Dr. H. Savage, Sioux City; *Secretary,* Dr. George F. Roehrig, Denver. On the evening of August 29, a complimentary banquet was tendered Dr. T. P. Livingston of Plattsmouth, Neb., the retiring medical director of all the Burlington lines west of the Missouri River.

Ohio State Medical Association.—The sixty-second annual meeting of this association was held at Cedar Point on August 28-30, under the presidency of Dr. B. R. McClellan. The election of officers resulted in the choice of the following: *President,* Dr. Charles L. Bonifield of Cincinnati; *Vice-Presidents,* Drs. D. W. Steiner of Lima, I. S. McClellan of Bellaire, A. B. S. Bowman of Akron, and H. F. Sutton of Zanesville; *Secretary,* Dr. J. H. J. Upham of Columbus; *Treasurer,* James D. Duncan of Toledo.

The National Association of Negro Physicians held its annual meeting in Baltimore the last week in August, under the presidency of Dr. F. N. Morrill. The meeting was opened by an address of welcome by the Mayor of Baltimore. The election of officers resulted in the choice of Dr. W. H. Wright of Baltimore, *President,* and Dr. Kenney of Tuskegee, *Secretary.* The next annual meeting will be held in New York in August, 1908.

"The Canadian Journal of Medicine and Surgery" for September is the annual illustrated number, published this year in connection with the meeting at Montreal of the Canadian Medical Association, which took place on September 9-11. In addition to the usual number of scientific contributions, there are forty pages of half-tone illustrations of the hospitals, sanatoria, and public institutions of Canada, as well as a number of views showing some of the beauty spots of the Dominion.

Dr. Thomas F. Harrington has been appointed director of physical training and athletics in the Boston public schools; Dr. Margaret E. Carley was appointed at the same time supervising nurse of the schools.

Obituary Notes.—Dr. Robert J. Young of Abbeville, La., died on August 31, at the age of nearly forty-two years. He was born in Abbeville on October 10, 1865, his father, Dr. F. D. Young, being one of the leading physicians of the parish at the time. He was graduated in arts from Grand Cotean College, and studied medicine first at Tulane University and later at the Hospital College of Medicine, Louisville, from which he received his de-

gree. Not only his father, but four of his brothers, were medical practitioners.

Dr. John Sidney Dyer of Boone, Iowa, died August 31 at St. Anthony's Hospital, Denver. He was born March 10, 1882, at Boone, and was graduated from the Northwestern University Medical School, Chicago, in 1905.

Dr. Charles J. Sorsen of Calumet, Mich., died in London, September 1. He was born in Finland, March 12, 1870, and was graduated from Rush Medical College, Chicago, in 1898.

Dr. Alexander Adler died in San Francisco, September 4, after an illness of several weeks' duration. He was a graduate of the University of California in the class of 1903.

Dr. Frederick J. Beckwith, health officer of New London, Conn., died of heart disease while making a professional visit, on September 2. He was born August 23, 1855, and was graduated from the Harvard Medical School in 1882.

Dr. Samuel Lewengood of this city died September 10 after a short illness. He was forty-five years old. Dr. Lewengood had practised medicine since 1882, when he was graduated from the Bellevue Hospital Medical College. He was a member of the American Medical Association and of the New York State and County Medical Societies.

Dr. A. Warner Shepherd of Brooklyn died at his summer home at Fort Hamilton on September 8, at the age of seventy-five years. He was born in Nashua, N. H., and was a graduate of the Long Island College Hospital in 1866.

Dr. Edward P. Nichols of Killingworth, Conn., died September 3, at the age of eighty years. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1851. He represented the town in the State Legislature for several successive terms, and was for twenty years medical examiner of Killingworth.

Dr. John H. Swasey of this city died in Portland, Me., on September 13, in his fifty-eighth year. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1875. He was a member of the New York County and State Societies, of the New York Academy of Medicine, and of the New York Pathological Society.

Obituary.

FRANCIS H. MARKOE, M.D.

NEW YORK.

After a painful illness of several months' duration, Dr. Francis Hartman Markoe of this city died on September 13 of aortic aneurysm. He was a son of the late Dr. Thomas Masters Markoe, and was born on March 20, 1856. Dr. Markoe was graduated from Princeton University, and received his medical degree from the College of Physicians and Surgeons in 1879. He at once became a member of the faculty of the school, and maintained this connection until the time of his death. From 1880 to 1884 he was an assistant demonstrator of anatomy; from 1884 to 1887 he was a demonstrator; from 1887 to 1900 he was a clinical lecturer in surgery; from 1900 on he was professor of clinical surgery. Since 1880 he had been attending surgeon to St. Luke's Hospital, and he had also been consulting surgeon to the New York Orthopedic Hospital and attending surgeon to the New York and Bellevue Hospitals. Dr. Markoe was a member of the New York Academy of Medicine, the New York County and State Medical Societies, the New York Pathological Society, the New York Surgical Society, the New York Medical and Surgical Society, the Physicians' Mutual Aid Society, the Society for the Relief of Widows and Orphans of Medical Men, and the American Surgical Association. He was also a member of the University, Union, Metropolitan, New York Yacht, Century, and Princeton clubs.

To his rare technical skill as a surgeon, Dr. Markoe joined unusual soundness of judgment and breadth of view gained through years of experience in general practice. For his students and assistants he was an example, not only of the ideal instructor and operator, but also of the highest type of manhood, while his patients found in him a wealth of sympathy and charm of personality that rendered his ministrations doubly helpful.

JAMES CARROLL, M.D.

MAJOR AND SURGEON, U. S. ARMY.

Dr. James Carroll died in Washington, on September 16, of a cardiac affection from which he had suffered since 1900. While serving with Major Reed on the yellow fever commission in Cuba, he voluntarily submitted to the sting of a mosquito which had previously bitten three persons having yellow fever. Four days later he was taken with a severe attack of the disease, thus confirming Finlay's theory of the rôle of the mosquito in spreading yellow fever. The disease did not kill him, as it did his colleague Lazear, but it left him with a permanently crippled heart.

Dr. Carroll was born in England in 1854, but came to this country in early life. In 1874 he enlisted as a private in the U. S. Army, and was soon promoted to be a sergeant. He was for fifteen years a hospital steward, studying medicine in his leisure moments. In 1891 he was graduated from the Medical Department of the University of Maryland, and then took post-graduate courses in pathology and bacteriology at the Johns Hopkins Hospital. He was then appointed contract surgeon, but in 1902, in recognition of his services on the yellow fever commission, the age limit was waived and he was allowed to appear for examination for admission to the Medical Corps, and was appointed first lieutenant and assistant surgeon. In March of the present year Congress passed a bill authorizing the promotion of Dr. Carroll to be major and surgeon in the regular army. Owing to his cardiac disability, Dr. Carroll was not fit for active service, and was appointed curator of the Army Medical Museum.

It is pleasant to think that Dr. Carroll's promotion came in time to make happy the last months of his life and to give him the gratification of knowing that his services in the cause of science and of public health were recognized and appreciated by a grateful country.

Physicians' Fees in France.—At the present day in the French provinces the fee for a visit is from three to five francs, with an additional franc per kilometer of distance from the doctor's house. In Paris the fees vary from three francs in the workmen's quarters to five francs in the better parts of the town. A general practitioner in Paris, in a good quarter, often earns £1,200 a year. There are some 200 who earn £1,000 a year; 400 to 500 who make from £600 to £800, and 2,000 who earn from £320 to £600. In the provinces, except in the case of beginners, the minimum seldom falls below £400 for a doctor who has a horse and carriage to command. Those who have a considerable reputation, and who work hard, may make from £800 to £1,200 a year. For consultations the usual fee to hospital physicians and surgeons is £2, and to those who have the title of "professor" £4.—*British Medical Journal.*

Correspondence.

THE HYPNOTIC ACTION OF APOMORPHINE.

To the Editor of the Medical Record:

Sir:—In an article by Dr. Rosenwasser of Newark, N. J., in your issue of July 27, it is stated: "To Dr. Charles J. Douglas of Boston belongs the credit of first calling the attention of the medical profession to the fact that apomorphine in non-emetic doses is an exceedingly valuable hypnotic."

In your issue of September 14 Dr. Tuckerman expresses the opinion, based on the records of a case treated by his father, that the hypnotic action of apomorphine was "fairly generally known" several years prior to the first publication of papers on this subject by Douglas (1899).

Immediately after the publication of my first paper on "Apomorphine as a Hypnotic," I sent a circular letter to a number of prominent physicians asking for information on the subject. I received over fifty replies, but not one of these physicians had ever heard that apomorphine had any hypnotic properties. In the edition of Potter's Materia Medica published that year (1899) occurs this sentence: "Apomorphine, though a derivative of morphine, is neither hypnotic nor narcotic in any degree" (p. 304). In a careful examination of the standard medical literature of that period I failed to find any dissent from this opinion. In the literary contest of "Merck's Archives" my paper on this subject received the $50 prize, Dr. George M. Gould of Philadelphia being the chairman of the committee of award.

If Dr. Tuckerman's father knew prior to 1899 that non-emetic doses of apomorphine would produce sleep, he was very successful in keeping it a secret from the rest of the profession, for it certainly was not "fairly generally known" before that date. C. J. Douglas, M.D.

Dorchester, Mass.

THE INTERNATIONAL CONGRESS OF PSYCHIATRY AND NEUROLOGY.

(From Our Special Correspondent.)

Amsterdam, September 4, 1907.

The International Congress of Psychiatry, Neurology, Psychology, and Nursing of the Insane was duly opened on September 2 in the *Concertgebouw* before a large audience in the presence of the Queen of Holland and the Prince Consort. The Minister of Justice, Dr. E. E. Van Raalte, explained the purpose and scope of the Congress and officially declared it open. He was followed by the president of the Congress, Prof. G. Jelgersma, M.D., who made the opening address. Immediately before the entrance of the royal pair and their attendants, a choir of over 250 voices sang the Holland national hymn, and during the afternoon sang selections from Händel's oratorios, Joshua and The Messiah.

At the close of Prof. Jelgersma's address Queen Wilhelmina and Prince Hendrik withdrew to a small parlor, attended by the ladies in waiting and many military attachés, where a very brief reception was held, at which some of the delegates were presented to her majesty. After the departure of the royal party from the building the proceedings of the opening session were resumed. The president called the roll of countries represented, and a delegate responded briefly for each, with few exceptions. MacDonald of New York, chairman of the U. S. national committee, having been prevented from reaching Amsterdam before the morning of the opening day, Beyer of the U. S. Navy was selected to respond for America. Bechterew of St. Petersburg responded for Russia, and Shima of Kioto for Japan. Perhaps the wittiest and most enjoyable response was made by A. Marie for France. An interesting circumstance known to few of the delegates is the fact that a convention of anarchists is being held in this city, including representatives from Poland, Germany, Russia, and all the supposed hot-beds of the foes of government. Extraordinary precautions have been taken by the authorities during the presence of the Queen in this city. Scattered here and there through the audience in the concert hall were numerous detectives and policemen in plain clothes. Two of these protectors appeared at each side of the great organ. Evergreen trees were placed at corresponding points in the side galleries of the hall, about fifty feet back of a line drawn through the chairs placed for the royal pair, and no one was allowed to go forward of these trees in the galleries. They, as well as the pots of palms and decorative plants, and also the brilliant mass of roses that formed a broad border along the edge of the large stage, were searched by the police for possible explosives. The royal party showed none of the nervousness that was felt; but it is an admirable characteristic of the Dutch to show, and in fact to permit themselves, no perturbation even in the face of actual danger. Many a delegate would have felt no surprise if some of his long-haired or scowling confrères had been apprehended as anarchists, so astonishing are the resemblances of genius.

The work of the sections is half done. Some changes from the earlier program have been made, and many valuable papers and discussions have been enjoyed. Mabon's paper on "The Open-air Treatment in Psychiatry" was read by MacDonald of New York and received with much interest. MacDonald, Hurd of Baltimore, Hughes of St. Louis, and Blumer of Providence took part in the discussion of the "Organization of Hospitals for the Insane and State Supervision," an able paper read by Ruysch of The Hague.

A most interesting paper on "The Reform of Nursing of the nsane in the United States," by Cowles of Boston, was read by Blumer of Providence. Shuttleworth and Seymour Tuke of London, and Ley of Belgium, contributed valuable papers on the topic of nursing the insane. The American delegates actually in attendance upon the convention are Beyer and White of Washington, Blumer of Providence, Brush and Hurd of Baltimore, Camp and Keen of Philadelphia, Southard of Cambridge, Wolfe of Norristown, Hughes of St. Louis, and MacDonald, Robinovitch, Ferris, Gregory, and Jelliffe of New York.

The perfect organization, smooth progress, and absolute care of all details which characterize the convention are due in the largest measure to the very efficient secretary, Dr. Van Wijenburg, with Van Deventer and several active and efficient assistant secretaries.

The broad hospitality and courtesy shown by the Burgomaster and also a number of ladies who received the delegates at their first social gathering added greatly to the social success of the Congress.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PLAGUE PREVENTION—CROONIAN LECTURES—INOCULATION SUCCESS—NEED OF A SPECIAL SERVICE—MALARIA IN MAURITIUS.

London, August 30, 1907.

It is only natural that the King's letter and the Indian Secretary's despatch, reported in my last week's letter, should have raised the subject of plague to a more important place in the public view than had been accorded to it. For unquestionably the Indian Government needs the support of the home authorities and of the general public in its efforts to combat the epidemic. It is very unfortunate that the cooperation of the native population is so difficult to obtain and that too often the efforts of sanitarians have been frustated by prejudice. Still, notwithstanding this, the Indian government has not been insensible of its obligations, and it is hardly fair of newspaper critics who have previously paid no attention to the matter to denounce both home and Indian responsible authorities as unequal to the situation the moment the King's letter arouses them to the tragic importance of the question they have allowed to be smothered by partisan politics. One must, however, admit as reasonable the doubt expressed by the Indian Secretary's despatch to the Viceroy as to "whether everything that can be done has been done," and further, "whether the last word of medical science and administrative skill has really been said." The despatch goes on to express a desire that no effort should be spared to arrest the spread of the epidemic by any means acceptable to the people, and adds that within reasonable limits of cost any proposals made for this purpose will be supported.

What has been done and what can be done are points which were treated in his recent Croonian lectures at the College of Physicians by Dr. W. J. R. Simpson, an acknowledged expert who was employed by the government as a commissioner to inquire into the Hong-Kong epidemic. He referred to a paper he submitted to the first Indian Medical Congress (1894) and the discussion thereon which resulted in the proposals by a deputation to the government to establish a special sanitary service of medical persons trained in the Indian colleges in preventive medicine. This was two years before the present epidemic broke out, when, as the service had not been organized, laymen had to be employed, and Dr. Simpson thinks this fact accentuated the opposition of the natives. He accorded the fullest credit for the efforts made to check the outbreak, but found the measures adopted too much actuated by the view that infected persons and clothing were the chief agents in disseminating the disease. He directed attention

to the way in which Madras has escaped for ten years where the sanitary administration has been left to the control of Col. King, I.M.S., who has pursued an active policy fully supported by the local government.

Is it possible to deal with plague as it now exists in India by effectual measures applicable to Hindus and Mahomedans and their mode of life? To this question Dr. Simpson answered yes. But the sanitary conditions have to be taken as they exist and they are similar to those of Europe in the fifteenth century, besides which the habits, prejudices, and religious scruples of the people must be considered. It is impossible suddenly to change the thoughts and habits of the people, or the condition of their dwellings, or their dislike of removal to hospitals. But these communities cannot defend themselves against plague without the intervention of government. Many schemes which have been proposed would take years to carry out. Meantime the people are perishing. It may be taken as an axiom, said the lecturer, that without a specially trained agency to direct and control the essentials are forgotten or misapplied and often useless measures are adopted. Without this agency the blind are leading the blind. It is pitiable to read some of the suggestions made, adopted, and carried out in good faith as likely to check the epidemic. Professor Simpson went on to show that an organized staff and a policy are the first essentials for combating plague and what are the measures which should be adopted to protect healthy districts and to deal with infected localities. As to these last he declared the only measures on a large scale were inoculation, evacuation and disinfection of dwellings, and destruction of rats. As to the first he cited the success of the splendid inoculation campaign in 1902 in the Punjab. It was planned to inoculate 7,000,000, but time and organization did not permit all this. Still half a million were inoculated and the mortality reduced to one-twelfth of that of the non-inoculated, and so 13,000 lives were saved in that season.

Inoculation and the evacuation of an infected locality, the lecturer declared, would stop any epidemic, and evacuation was necessary in a village in which no means of disinfection with rat destruction existed. But the first thing required was the specially trained plague service, organized on correct lines and on a liberal scale. This he concluded must be done quickly if more stupendous disasters are not to follow those of the present year.

Malarial diseases have been so excessively prevalent of late in Mauritius that Major C. E. P. Fowler, associated professor in the Royal Army Medical College, has been appointed to inquire into the matter.

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

SEVENTH ANNUAL MEETING OF THE SCANDINAVIAN MEDICAL CONGRESS—PROSTATIC OPERATIONS—REMOVAL OF MALIGNANT GROWTHS OF THE ESOPHAGUS—INFLUENCE OF LUMBAR ANESTHESIA IN THE UTERINE FUNCTION—TRYPSIN IN CANCER—X-RAY DIAGNOSIS OF SINUS DISEASE—FIFTIETH ANNUAL MEETING OF THE DANISH MEDICAL ASSOCIATION—FINSEN LIGHT TREATMENT OF LUPUS.

COPENHAGEN, August 29, 1907.

At the recent seventh annual meeting in Christiania of surgeons from Denmark, Finland, Norway, and Sweden many interesting subjects were discussed. The most important topic chosen was perhaps the question of prostatectomy as relief operation in urine retention caused by hypertrophy of the prostate. Here Dr. Gundersen, a Norwegian colleague now practising in La Crosse, U. S. A., advocated prostatectomy by the perineal method, having himself operated successfully in forty cases. He strongly recommended Young's technique. Dr. Jewell of Christiania preferred the suprapubic way, Freyer's operation. Prof. Th. Rovsing of Copenhagen would perform prostatectomy only in a few strictly selected cases. He thought that too little attention was generally paid to the important physiological function of the prostate by those who have made a routine operation of prostatectomy. The prostate was necessary to preserve the sexual origin, and it was not to be treated as a matter of no consequence whether or not a man became impotent at the age of say fifty or sixty. There were also on record cases of insanity occurring after prostatectomy had been done. In most cases, where an operation was necessary in order to give the patient relief, he performed a suprapubic cystostomy and had through this opening a Pezzer's catheter à demeure. By means of this little and innocuous operation he had enabled more than one hundred patients to lead a happy and contented life. In certain forms of hypertrophy, of which he gave an exact description, he had performed vasectomy (somewhat less than 100 patients).

At the same meeting Prof. Tscherning of Copenhagen demonstrated an operation he had devised for the removal of malignant new growths of the upper part of the esophagus and the adjacent part of the hypopharynx. The new feature about his method is that he splits both the anterior and the posterior wall of the larynx and of the upper part of the trachea by a longitudinal incision in the middle line, thus avoiding a lesion of the nerves, vessels, muscles, etc., of the lateral regions of the neck. The tryoid bone is also divided in the middle line. Retractors are then inserted on the pharyngeal side of the divided cartilages, and it is now very easy to evert the whole of the mucous membrane of the hypopharynx and of the upper part of the esophagus. As all incisions are made in the middle line, the bleeding is practically nil, and facility of inspection of the region in question afforded by Tscherning's operation is just as great as if a laryngectomy had first been performed, and far greater than that attained by lateral or transverse incisions.

Prof. Westermark of Stockholm reported some interesting observations he had made on the influence of lumbar anesthesia on the uterus during delivery. He had observed that the inferior segment of the uterus became paralyzed, while the upper segment continued to contract. These observations confirmed what anatomical investigations had taught him, viz., that the inferior segment derived its innervation from the lumbar region of the spinal cord, while the upper segment was without any nervous supply, contracting only as a result of properties appertaining to the muscles alone.

Dr. N. Rh. Blegvad of Copenhagen communicated a note on ten cases of malignant new growths treated by trypsin injections. Only in one case the patient seemed to have derived some benefit from the treatment, as the discharge became less profuse and foul. In more than one case disagreeable symptoms set in, and the result of the trial had not been encouraging at all.

Dr. P. Tetens Hald of Copenhagen read a paper on *x*-ray pictures as a help to the diagnosis of affections of the accessory sinuses of the nose. His series of lantern pictures illustrated very well how the outlines of the affected sinus become indistinct and hazy and the whole sinus takes a blurred appearance. He recommended strongly to compare the bitemporal picture with the fronto-occipital one and related examples of cases in which this comparison had helped to the correct diagnosis.

On August 22 and 23 the Danish General Medical Association celebrated its fiftieth anniversary. The most important event of the meeting was the incorporation of the Association of Junior Medical Men with the older organization. The last-mentioned body counts as members nearly all Danish medical men not yet in practice, who are in the hospitals, in the scientific institutes of the university, etc. As a result of this incorporation the Danish General Medical Association comprises now in its ranks practically all the 1,600 to 1,700 medical men of Denmark, and will consequently be able to do much good as well for the public as for the profession itself.

At this meeting an interesting demonstration of one hundred cases of lupus, never before shown at any congress, was made by the director of the Finsen Light Institute of Copenhagen. Dr. Forchhammer, reviewing the different methods of treatment, said that the *x*-ray could, in certain cases, especially of hypertrophic lupus, effect a cure, but recurrence was often observed. The best local treatment hitherto known was the Finsen light treatment. In obstinate cases, more than five years old, too much must not be expected; but even in these cases the patients were, as a rule, considerably bettered and the spreading of the destruction prevented. In more recent cases, of less than five years' duration, the result was practically all that could be wished for. Of 500 cases in this class treated in the Institute, 53 per cent. were cured, and the cure had been verified by an observation of not less than two years. Other 22 per cent. were also cured, but the observation had not been long enough to make sure whether relapses would occur or not. Of the 12 per cent. yet under treatment some might perhaps not get cured, as they had severe affections of the mucous membranes, especially at the interior of the nose. In the remaining 13 per cent. the treatment had been discontinued; one-half of these patients had died.

One of the attractions of the meeting was formed by a historico-medical museum, created by Prof. Carl Y. Salomonsen and Dr. Johnssen, who had succeeded in bringing together quite a large and valuable collection of old medical and pharmaceutical implements, instruments, prints, books, autographs, etc.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 6, 1907.

Lead Poisoning in a Rural Community.—The paper of W. N. Cowles is a recital of clinical histories of cases of lead poisoning which have occurred in a group of adjacent towns in Eastern Massachusetts. The acute cases are few. The majority are of a chronic nature, exhibiting various painful and disabling affections and arteriosclerosis. The author believes from his experience that many instances of vague abdominal troubles and of painful and crippling affections commonly called rheumatic, are in reality cases of lead poisoning. In one of his cases the patient was poisoned by water from a well in which, two years previously, an old lead clock weight had accidentally been dropped. Removal of the weight was followed by immediate improvement of the patient, although she continued to use the well water. In most instances, however, the lead pipe in a well goes several feet into the water, thus giving considerable extent of surface for the action of the water on the metal. Naturally the composition of each particular water will determine its amount of action on any lead pipe with which it may come in contact. The substitution of iron for lead pipe is the only safe course.

New York Medical Journal, September 7, 1907.

The Prevention of Deafness.—After some statistics as to the frequency of deafness, W. Scheppegrell discusses the etiology of the affection, referring particularly to infection from the nasopharynx, foreign bodies in and injuries of the external meatus, catarrhal processes, aural suppurations, nasal obstruction, etc. Prophylaxis of deafness naturally implies the removal of its various exciting causes. Early recognition of ear complications in the exanthemata is of the greatest importance. A strong plea is made for the systematic examination of the ears of school children. Much good advice to the general practitioner is given, but the paper presents nothing new whatever.

The Neurasthenic Neuralgias.—By this term F. H. Hallock refers to a class of painful peripheral affections occurring in neurasthenic or allied conditions. Anatomically, this class may be divided as follows: (1) Trigeminal; (2) cervicooccipital; (3) cervicobrachial; (4) brachial; (5) intercostal, including mastodynia; (6) lumbar plexus, including lumboabdominal and regions supplied by the cutaneous femoris lateralis, cruralis, and obturatorius; (7) sacral plexus, including sciatica, neuralgia of the genital organs and of the anal region; (8) coccygodynia; (9) achillodynia, tarsalgia, and metatarsalgia. Clinically, these varieties lie midway between the more or less indefinite and subjective paraesthesiæ and the very definite and objective conditions resulting from neuritis and other pathological irritations. The clinical diagnosis between actual neuritis and neuralgia may be summarized as follows: The motor element is the chief distinctive characteristic. In neuralgia there is no true loss of power and the pain does not materially restrict the movement or manipulation of the affected part. In neuritis proper the motor disability is present in some degree, and varies from paresis to paralysis. Both motor and sensory symptoms occur earlier and are more sharply defined in neuritis, the swelling of the nerve being more evident and continuous throughout its length and without the presence of the points of Valleix. The pain itself is generally more continuous in neuritis and more paroxysmal in neuralgia. Atrophy and anesthesia occurring with the paralysis are not present in neuralgia. The ailment calls for attention to the underlying neurasthenic state and the management of the local condition. Rest is essential. The nutritional processes of the affected parts must be improved by massage—electricity, douches, dry hot air, etc. Voluntary exercise should be allowed gradually. The medical treatment is unsatisfactory. Morphine has a characteristically bad effect on this class of neuralgias. The best analgesics are antipyrine, acetphenetidine, gelsemium, and the salicylates. In the lesser paroxysms a small dose of bromide may be enough to allay the nervous irritability and thus allow relaxation to the pain. It is advisable during the attack to do something for, or with, the patient. Thus the act of bathing the feet in hot water, rubbing the part with menthol dissolved in a fit menstruum, using mild liniments applied alone or with heat, flushing the bowel, these and other procedures help to distract the attention and so enable milder drugs to be more effective.

Journal of the American Medical Association, September 14, 1907.

An Epidemic Pneumococcal Catarrhal Disease.—H. G. Beck and W. R. Stokes give an account of a peculiar epidemic that has appeared in two separate years in Baltimore. The disease exists as a distinct entity, occurs in the spring months, though similar epidemics have occurred in the autumn, and is characterized by purulent or fibrous inflammation of the mucous membranes of the eye, nose, and throat. There is a characteristic, usually spasmodic cough sometimes resembling pertussis. The disease commences with chilliness and slight fever, with sneezing, lacrymation, and mucous nasal discharge. There may be an associated bronchitis, but the symptoms indicate the chief trouble to be in the upper end of the air passages. There are no serious nervous symptoms and little or no physical or mental depression; the average duration is from one week to ten days, though the cough often continues longer. The disease is clearly infectious, running through families, and even animals do not appear to be altogether immune. It is distinguished from measles, pertussis, and influenza. Epidemic catarrh lacks the gastrointestinal symptoms, constipation, or diarrhea, due to the *Micrococcus catarrhalis*. So far as the eye symptoms are concerned, the disease is the same as the pneumococcic conjunctivitis described by Kölle and Wasserman as occurring in Europe in 1896. In most of the cases examined bacteriologically the pneumococcus was found, giving the usual culture and staining characteristics and producing characteristic effects in inoculation experiments. The authors recognize the fact that the pneumococcus may be considered as an almost constant inhabitant of the nose and throat, and when it is discovered, as here, in diseased conditions of the mucous membrane, usually in pure culture, frequently virulent, and so distributed in purulent and fibrous inflammations as to explain these conditions, they have no hesitancy, they say, in considering it as the cause of the condition.

Uric Acid Elimination.—L. B. Mendel and E. W. Brown find that the ingestion of a purin-free meal is followed by a minimal rise in uric acid output above the abstinence values during the hours immediately following the ingestion of the food. When larger quantities of protein are included the rise is somewhat larger, but in none of these cases is the postprandial rise comparable in extent with that observed in later experiments with purin-yielding foods. The experiments also show that the rise is not attributable to simple increase of diuresis, as is shown in the tables. The influence of a meat diet was marked by a rapid increase of uric acid elimination and still more with glandular and other purin-yielding tissues. The residues left after extraction of free purins from meat afford only a small rise. The factor, heretofore underestimated, of the rate of discharge of different foods from the stomach as influencing the results, is noticed and the need of more definite information remarked on. The character of the test meal is clearly of influence on the type of postprandial elimination, but further studies are required of the effects in pathological conditions.

Dynamic Ileus.—J. C. Munro emphasizes the fact that dynamic ileus is nearly always the result of sepsis of the peritoneum or of a toxin affecting the motor mechanism of the intestine. A purely functional paralysis of nervous origin may exist, according to Nothnagel, but it is rare. The nonfatal distention following blunt contusion of the abdomen may be due to a reflex or functional cause, but it is more reasonable to suppose it due to the contusion of a loop of gut or its mesentery, too slight to produce the usual necrotic changes. The distention and obstruction seen in abdominal disorders, before operative interference, are usually due primarily to a peritonitis; the same is true in the fulminating ileus after operation; though the superficial evidences may be slight, the omentum and mediastinal glands will show the presence of abundant microorganisms. It is remarkable how slight a peritonitis will stop peristalsis, especially in cachectic and anemic individuals. It is not safe to exclude some degree of sepsis as a cause even of ileus after a clean aseptic laparotomy, and it is worth noting that patients with pre-existing septic foci who have acquired a certain degree of immunity suffer comparatively little from distention, while a very slight intraabdominal operation in an acute case, before immunity is acquired, will arouse an intense ileus. On this account, delay in operating on septic diseases of the peritoneum is sometimes wise. That toxins independent of those from an intraabdominal lesion may produce ileus is shown by the cases of distention seen with pneumonia, and, more rarely, in acute nephritis. Either of these may be confused with the ileus of abdominal inflammation, but the distinguishing sign of surgical spasm is absent in these cases. Distention alone is of moment, as toxins

can penetrate a healthy intestinal wall when distended and produce peritonitis, and the toxins from an obstructed intestine are far more virulent than those from a healthy gut. Another cause of ileus that the surgeon must remember is mechanical injury to the intestine or its mesentery. Manipulation is far more injurious than mere exposure or anesthesia. The cessation of intestinal activity here is apparently a conservative provision to allow repair to take place and peristalsis to be reestablished. Munro cautions against the use of cathartics, except to a very slight extent, in all cases of so-called obstruction in which there is any suspicion of its being mechanical or infective. In the milder peritonitic types it is better to rely on the elimination of the intestinal contents from below. If there is a definite local focus it requires attention, but it is rarely necessary to meet reflex or toxic ileus by other than palliative means, or aperitonitic or traumatic ileus by operation for the ileus alone. Any type, however, may be so rapidly fulminating as to call for operation, and here the surgeon's judgment must decide.

The Larynx in Locomotor Ataxia.—W. B. G. Harland found very little serious trouble of the larynx of the tabetics examined by him in the Philadelphia General Hospital and the Philadelphia Home for Incurables. He was unable to find a tabetic patient with laryngeal crises, and neurologists of his acquaintance tell him they have rarely seen such. His conclusions are given as follows: 1. The larynx is seldom seriously affected in locomotor ataxia. 2. Rarely, early in the disease, spasmodic abductor paralysis may sometimes arise, and should suggest to the laryngologist the possibility of tabes as its cause. 3. Late in locomotor ataxia one or the other cords (generally the left) is often found in a hyperabducted position.

Cleansing Treatment of Chronic Middle-Ear Suppuration.—W. S. Bryant has found in twenty years' experience that in the majority of cases chronic middle-ear suppuration will yield to cleansing treatment. He includes cases in which the infected area is spreading and also those with acute exacerbations, both rightly considered very dangerous. The cases that do not yield, he says, are those in which there is so much caries that it cannot readily be removed by natural processes; those in which there is active osteitis; those in which sepsis has spread outside the bone; those in which there is some special infection, such as syphilis or tuberculosis, and, lastly, those in which vital parts are involved, requiring immediate attention. In other cases, the essentials are proper drainage, and attention to the condition of the Eustachian tube, and the nasopharynx. If the drainage is sufficient and there are no collections of thickened material, dry wiping with boracic powder applications gives satisfactory results. Cheesy material should be wiped out, or syringed out with a strong solution of bicarbonate of soda in neutral salt solution. If this is not sufficient, suction may be employed, and the serous exudate and possible hemorrhage act as an antiseptic wash and help to remove some of the solid particles. A persistent dirty discharge may call for peroxid of hydrogen followed by salt solution, alcohol or silver nitrate. Caries should be treated by cleanliness, and feeble granulations be stimulated by silver nitrate. For this, astringents are advised.

Serum Diagnosis of Syphilis.—P. Fleischmann and W. J. Butler explain the principle and method of the serum diagnosis of syphilis, developed by Wassermann, describing in detail the technique and giving their own results with its employment. The method is based on the phenomenon of the fixation of complement first observed by Bordet and Gengou, and is somewhat complicated, but it demonstrates the existence or specific antibodies in probably all cases of active existing syphilitic infection, and the authors consider it of incontestable value as a diagnostic measure. In thirty-eight cases with a history of syphilis the reaction was positive in twenty nine and inquiry revealed that the other nine patients were either under active treatment or had undergone such. In no case with active manifestations did the reaction fail, except in cases of tabes, in which disease it is possible that the symptoms may persist on account of irreparable injury after disappearance of the antibodies. The authors think that a positive reaction with this test may be considered a sure indication of syphilis, a point of especial importance in diseases in which the determination of their etiologic relations to syphilis is in question. The importance of the test as regards contagiousness, urgency of treatment, prognosis, etc. is not so definite, but they think they do not err in saying that the demonstration of antibodies is a tenable indication for treatment. On the other hand, one cannot say at present how far we can use the disappearance of antibodies in judging a cure. During or after treatment, it is true, there is only a slight reaction or none at all, but more experience is needed before the full significance of this fact can be estimated. More study of the subject, which they think has not received as yet due consideration, is needed, and the hope of stimulating other similar investigations has been their chief incentive in this publication.

British Medical Journal, August 31, 1907.

Clinical Pathology in Relation to Diagnosis and Treatment.—C. B. Lockwood discusses in this connection the respective rôles of the diphtheria bacillus, *Streptococcus, pyogenes, Staphylococcus, pyogenes aureus,* pneumococcus, colon bacillus, and the early diagnosis of cancer by immediate histological sections. Under the former headings are mentioned some of the less common forms of infection by the respective microorganisms. The immediate examination of sections made by the freezing microtome, of new growths, the author regards as of the greatest importance, especially in mammary neoplasms. No one can positively diagnosticate certain of these with the naked eye. Small cancers, small adenomata, and small cysts may all present the same physical characteristics. The author makes a plea for bacteriological examination in all cases of inflammation where such a thing is possible. Very unexpected findings are sometimes the result. The diphtheria bacillus especially may be unexpectedly encountered and as we now have a specific therapy for this disease the importance of an early diagnosis is at once apparent.

Open-Air Treatment of Pneumonia.—G. E. Rennie states that the two main points in treatment are, first, to maintain heart action against the depressing effects of the toxins of the pneumococcus, and, second, to prevent imperfect aeration of the blood. He believes that these two indications are most effectively met by the adoption of the open-air method. His hospital plan of treatment (New South Wales) is to place the patients on the balcony or veranda of the hospital, where they are kept night and day. A screen is placed around the head of the bed to keep the cold winds from blowing directly on the patient. Of the cases thus treated, in all about twenty in number, only one has proved fatal, and that was an old man over sixty years of age, who was admitted practically moribund, with extensive consolidation, much cyanosis, and a very feeble pulse. He died within a very few hours after admission. In no case has the open-air plan seemed to give any unfavorable results, but rather has seemed to have a beneficial effect on all the symptoms. The temperature has never risen above 103.8°, and no antipyretic treatment has been necessary. In most of the cases the temperature dropped and the crisis occurred in two to three days. In no case so far has the crisis occurred later than one week from the onset of the disease as estimated by the initial rigor. The author does not wish to be understood to claim that this line of treatment has any special effect on shortening the duration of the disease; he merely states what has been his experience. An investigation of a much larger number of cases treated by various methods would be necessary to enable one to decide whether the disease is really shortened or not by open-air treatment. As regards the pulse, an almost immediate effect was noted in the way of improvement, and in only a very few instances was any cardiac stimulant, such as strychnine or digitalis, needed. No alcohol has been given. The tongue began to get moist and to clean rapidly, and the appetite was much improved; the patients were always ready for their milk. Sedatives have not been required except in one or two instances where there was some delirium at first, but not more than one dose has been requisite. As a rule sleep became at once quiet and refreshing. Cyanosis also rapidly disappeared.

Münchener medizinische Wochenschrift, August 20, 1907.

The Relation Between Pneumonia and Gout.—Ebstein, after discussing the literature on this subject, relates the history of a patient in whom the pneumonia seems to have been the direct cause of an attack of gout. The patient was a man fifty-six years old, who was admitted into the hospital with a double-sided pneumonia, and who had his first attack of gout seven years before. The pneumonia took a protracted course and five weeks after its onset the patient developed a typical attack of gout. Ebstein explains this relationship by the fact that an increased

amount of uric acid is produced by the nuclear destruction which takes place during pneumonia; this increased amount of uric acid in the blood then causes the attack of gout in people disposed to it. He believes that this class of cases is rare and must be differentiated from those in which a pneumonia sets in at the end of an attack of gout; both, however, show that a relation exists between gout and pneumonia, and that the one following the other is not merely a coincidence.

Potassium Iodide and Mercury in the Treatment of Tuberculosis of the Nose, Throat, and Larynx.—Grunberg refers to his previously published good results in primary ascending tuberculosis of the upper air passages with potassium iodide. He relates the history of four cases of ascending tuberculosis in which a clinical diagnosis only was made, and which Martin cured with mercury injections, and then reports a case of his own, in which he made a clinical diagnosis of tuberculosis of the palate, pharynx, and larynx, the diagnosis being substantiated by microscopical examinations and by producing tuberculosis in guinea pigs with a piece of diseased tissue. The patient was at first given thirty grams of potassium iodide per day for five weeks and then mercury hypodermatically for three months, at the end of which time he felt well, had gained in weight, had no further subjective symptoms, and showed only slight changes in the larynx. In other words, the patient was practically cured. The mercury treatment was begun after the patient showed no further improvement with the iodide treatment. Grünberg believes that this case proves the healing qualities of mercury in tuberculosis of the upper air passages; it could hardly be called a spontaneous cure on account of the short time in which the cure took place. Of course, there may have been an element of syphilis in the case, but even then it must be admitted that as the patient was practically cured the mercury also had a good effect on the tuberculous process. He concludes by saying that in cases in which there is a doubt as to diagnosis, good results with iodide and mercury no longer point to a positive diagnosis of syphilis.

Hysterical Sweating.—Curschmann relates the history of two cases in which regular, spontaneous, recurrent attacks of sweating occurred and which were not caused by emotions or exercise; they came on at a time of mental and bodily rest, but not during sleep. The first patient was fifty-seven years old and claimed to have had influenza each year for twenty years; these attacks consisted only of headache, weakness, and recurrent sweats. Curschmann saw her in one of these so-called attacks of grippe, which lasted four months, and during which she perspired profusely three times a day; she had no fever, no loss of appetite, and gained in weight; the patient said she had to perspire or else she would feel sick. The second patient he observed was the daughter of the first, and had been subject to similar yearly influenza attacks for ten years. Electric baths and suggestion cured both. Their nervous system revealed no organic changes and hysterical stigmata were absent, and yet Curschmann believes the condition to have been nothing else than hysterical sweats, far different than the one we see in neurasthenic persons who get a hyperhidrosis of the hands at the moment they fear to get it, *i.e.* when they shake hands with other people.

Curative and Poisonous Action of Marmorek's Antituberculous Serum.—Baer relates the history of a case in which the treatment with Marmorek's serum caused peculiar symptoms. The patient was a young girl twenty-three years old, whose mother had died of tuberculosis of the lungs. She had been coughing for six years and showed tuberculous signs at one apex, though the tubercle bacillus had never been found in the sputum. She developed joint symptoms in the left knee, which were considered tuberculous, and as they did not respond to injections of iodoform and glycerine, it was decided to use Marmorek's serum. Five c.c. were given daily by rectum. On the sixth day of the treatment she complained of dizziness, palpitation of the heart, nausea, and vomiting, and developed a rise in temperature and pulse. Finally she became cyanosed and developed Cheyne-Stokes respirations. The treatment was stopped and when she recovered, after forty-eight hours, it was begun again. Similar attacks occurred on and off while the serum was used. After five months the knee was cured and the treatment was stopped. These attacks he explains by an overloading of the system with tuberculotoxins, which in this case originated in the knee; the curve of the opsonic index substantiates this view. For the first few days the index remained stationary and after a few days of serum treatment it gradually rose, to return to its original value when the treatment was stopped. Baer holds that the value of Marmorek's serum in tuberculosis is still doubtful and that poisonous effects such as his patient developed cannot be prevented at the present time. He thinks the action of the serum might possibly be controlled by carefully and continually watching the opsonic index during a course of treatment with the serum.

Deutsche medizinische Wochenschrift, August 15, 22, and 29, 1907.

Tuberculin Suppositories.—Lissauer maintains that, although the real value of the tuberculin treatment in tuberculosis is still uncertain, its administration by way of suppositories has several advantages and gives the same results as other methods of administration. The suppository is inserted after a movement or after a cleansing rectal irrigation, no aseptic precautions being necessary, while when it is given hypodermically the skin has to be carefully cleansed, and even then there is usually some local reaction. After a suppository has been given there is no fear of any infection, and a local reaction is rare, and when present manifests itself only by slight burning about the anus or a mild diarrhea. The action of tuberculin is more certain when given in suppositories than when given by inhalation or by mouth. The patients on which Lissauer tried the suppository treatment were usually advanced cases of tuberculosis with a poor prognosis. Koch's "Alttuberculin" was used and, as is the case with most drugs administered by rectum, somewhat larger doses of tuberculin were used than when it was given by mouth or hypodermically; the amounts were usually fractions of a milligram. The drug was given daily or every few days or at weekly intervals, depending upon the case. In patients which reacted the usual symptoms which follow the administration of tuberculin set in; their mode of onset, however, was slower and milder, hence suppositories can be safely given in far advanced cases in which severe, sudden reactions are undesirable and in which a propagation of the process would be caused by hypodermatic injections of tuberculin. Hemoptyses and skin eruptions were noticed several times after the use of suppositories. As a further proof that tuberculin causes a reaction in the lung tissue itself, he mentions patients with anthracotic lungs, in whom the sputum, which had been yellow, now became black, showing that changes were going on in the lung. As regards the therapeutic value of tuberculin, he admits that some patients were not benefited and that others might have gotten well without it, but firmly believes that loss of disagreeable subjective symptoms, an increase in body weight, and an improvement of the local lung condition could at times be attributed to tuberculin alone.

Double-sided Nephrolithiasis.—Krause reports a case on account of its rare occurrence and because of the difference in prognosis and therapy in one and double-sided nephrolithiasis. The patient was a man twenty-eight years old, who previous to his twenty-first year had always been well. At that time he suffered from left-sided renal colic and passed a small stone. At twenty-three he again complained of left-sided pain, which returned when he was twenty-six years old. Then it continued for almost a year, each attack lasting from eight to eleven days, a small stone being passed in one of them. A year later, in January, 1906, he experienced a pain in the right lumbar region for the first time, which was accompanied by some bloody urine. An *x*-ray picture showed a shadow in both kidneys, none in the ureter or bladder. The right kidney was exposed and found much enlarged and congested; no stone was palpable. The pelvis of the kidney was then opened, when a stone was found and removed. Six weeks later the other kidney, in which the *x*-ray showed a stone in the lower pole, was opened and the stone removed. This kidney was also found enlarged and congested, the removal of the stone having been accompanied by considerable bleeding. Krause always advises immediate operation in double-sided nephrolithiasis on account of the constant danger of a hindrance to the flow of urine on both sides at once; furthermore, pathological changes in one kidney set in because the other, also containing a stone, cannot do compensatory work. He advises locating the stone exactly by the *x*-ray, and when the stone cannot be palpated during operation he advises looking for it by opening the pelvis of the kidney before sectioning the kidney tissue, since the latter procedure is often accompanied by a great deal of hemorrhage. He does not follow the usual custom of operating first on the kidney which was the seat of the last colic, but is guided by the functional activity of the kidneys, which he ascertains by clinical observation of the case, by kryoscopy, and ureteral catheterization. If the *x*-ray shows a stone in the kidney substance on one side and in the pelvis on the other, he operates on the latter kidney first on account of the greater liability of a complete obstruction of urine setting in.

He advises against doing a nephrotomy on one side when there is a stone in the ureter on the other side, as the increased amount of urine on the side of the ureteral stone might move the latter and wedge it more tightly in the ureter, thus causing a complete obstruction of the urine on that side. He therefore removes the ureteral stone before undertaking an operation on the kidney of the other side.

Etiology and Treatment of Postoperative Intestinal Disturbances.—Heile believes, on the strength of clinical material which he cites, that the diarrhœa which sometimes occurs a few days after operation, and which does not respond to antidiarrheal treatment, but runs into coma and even death, is due to a transient or permanent diminution of the total body alkali. A diminution of the body alkali usually manifests itself by the presence of acetone and diacetic acid in the urine. Due to long pyloric or intestinal stenoses, or to the toxins produced by malignant growths, a patient is poorly nourished and consequently cannot stand the loss of large amounts of alkali. If these patients are called upon to give up large quantities of alkali with the intestinal secretions in order to neutralize the intestinal contents, and finally cannot secrete enough to neutralize the latter, then a diarrhea sets in. The secreted alkali which neutralized the intestinal contents is excreted with the stool, while normally it is not lost after neutralizing the organic acids of the intestinal contents, but is reabsorbed by the large intestine. In these cases, where it is totally lost, coma sets in. Animal experiments show that the intestines secrete an alkali and that the amount of the latter depends upon the intestinal contents, being greater after a meat than after a mixed diet, and if an intestinal catarrh is present it will be still greater. If the large intestine is excluded in these animals, the alkali cannot be reabsorbed and consequently the animal loses weight and recovers only after being fed some alkali. In human beings, too, the amount of alkali depends upon the food and the condition of the small intestine. If diarrheas set in, the alkali does not get a chance to be reabsorbed by the large intestine, but is washed out of the system with the watery movement and the patient will go into coma and die unless the alkali is supplanted. Poorly nourished patients should therefore have their urine examined for diacetic acid and acetone before being operated upon and should be given an alkali as a prophylactic if these are found. When the diarrhea has once set in an alkali should always be administered in addition to regular antidiarrheal treatment.

How to Prevent the Retention of Packings in the Abdomen.—Wederhake mentions various methods used to prevent the retention of packings in the abdomen during laparotomies and then describes a method devised by himself which he believes will positively prevent such an error. He makes a many-tailed compress by taking one square yard of material, into which four cuts are made, one extending from the middle of each of the four borders of the material to within two inches of the center. In this way he obtains four packings in one piece. When more packings are required at an operation he uses an eight-tailed compress, making, in addition to the four cuts from the middle of each border, four others, beginning at the corners of the square yard of material, these again being carried within two inches of the center. He claims that only one compress is needed at an operation and that no packing can be left behind, as in order to remove one all have to be removed. As never more than one compress is used, the operator does not have to rely on his own count or that of his assistants in order to know how many packings were used.

Gastric Juice in the Fasting Stomach.—Gentzen carried out a series of experiments to prove that the normal fasting stomach contained gastric juice. For this purpose he employed Sahli's desmoid reaction. A desmoid pill containing methylene blue and closed with catgut was given to persons whose gastric secretion had previously been shown to be normal after the ingestion of a test meal. The pill were swallowed in the morning when the stomach was empty, not even a drop of water being given with them. In thirty-three out of fifty-three persons methylene blue was found in the urine in less than two hours after the ingestion of the pill, in fifteen in two to three hours, in two in four hours and in three in six to seven hours. In other words, the catgut had been digested, the contents of the pill had been poured out, and since the acid gastric juice is required to digest the catgut it must be normally present in the fasting stomach. Gentzen then refutes the objections advanced to his conclusion by various observers: (1) that the secretion of gastric juice was caused by the mechanical irritation of the pill; this he believes has been proven to be impossible by Pawlow's experiments in which he showed that mechanical irritation of the gastric mucosa does not cause any flow of gastric juice; (2) the claim that the catgut was dissolved in the intestine he proves to be untrue by first showing that the gastric juice of rabbits can dissolve catgut just as human gastric juice does. Then he inserted one desmoid pill into the upper portion of the duodenum of five rabbits and one into the lower portion of the duodenum of another rabbit. Two out of the five rabbits showed methylene blue in the urine in five hours, the rabbits in which the pill was inserted into the lower portion of the duodenum passed the pill *in toto*. In the latter case the reaction of the duodenal secretion had been tested and found to be alkaline. He thought the digestion of the catgut in the first two rabbits might have been caused by gastric juice which entered the duodenum; to exclude this possibility he repeated his experiments after having first ligated the pylorus. The animals died after sixteen hours and up to that time no methylene blue had been found in the urine. At autopsy the pill was found *in toto* in the duodenum. He likewise found that when keratin-coated desmoid pills were swallowed by persons they were found in the feces intact, but with the keratin dissolved. All these experiments showed that the catgut is not digested in the intestine and that methylene blue found in the urine within six hours after the ingestion of the desmoid pill must have been caused by the digestion of the catgut in the stomach; in other words, the human fasting stomach always contains some gastric juice.

The Contagious Character of Pointed Condylomata.—Neuberg reports the history of a case which in his opinion proves without doubt that pointed condylomata are contagious. A man twenty-five years old who never had a gonorrhea came to him with numerous pointed condylomata of the prepuce and glans and as he did not carry out the advised treatment he did not get rid of them. Eight months later his wife, who also never had a gonorrhea, consulted him and he found a similar condition of the vulva, which had developed only after coitus with her husband. The fact that neither patient ever had a gonorrhea surely proved the contagious character of these condylomata.

French and Italian Journals.

Treatment of Congenital Pseudoarthrosis of the Tibia.—A. Codivilla says that this lesion is most rebellious to treatment such as is used in the acquired form. In three cases operated on by him he has made use of different treatments, and none of these has resulted in a cure. The cause of the insuccess lies in an absolute absence of formative action in the osteoblastic tissues, especially the periosteum. Probably at a certain period of intrauterine life there is a lack of blood brought to the part and a lack of nutrition of the tibia, and the nutrition of the diaphysis is left to the subsidiary vessels of the part; that is, those of the capsule and the muscular structures connected with the joint, the circulation not extending to the location of the pseudarthrosis. The author presented radiographs which showed evidence of the osteoblastic insufficiency, and the anatomical report confirmed these appearances. Reichel has made use of a graft of normal tibia, and the author has tried this method of treatment without success. But by transplantation of a portion of normal periosteum in one case a cure has been obtained. He presented the patient and also exhibited a radiograph showing the attachment of the periosteal graft with the gradual formation of callus.—*La Riforma Medica*, June 15, 1907.

Treatment of Eclamptic Attacks by Lumbar Puncture.—Audebert and Fournier record two cases of puerperal eclampsia treated by them by means of lumbar puncture, and have collected forty four other cases. They believe that the cerebral symptoms, including convulsions and coma, are markedly affected by an increase in cerebrospinal tension, which has been observed in many cases. Cerebral lesions, such as congestion, hyperemia, and hemorrhages are commonly observed after death in such cases. Lumbar puncture with withdrawal of fluid should relieve cerebral tension, and bring about a decompression of the central nervous structures. This treatment will not affect the condition of the kidneys, which it will not reach. But it will relieve the symptoms due to cerebral pressure and thus aid in saving the patient. Such treatment is not to be used in every case, nor is it to be used alone as a specific measure, but should be combined with other methods that have been found of use in treatment. It should be instituted when coma is profound and when convulsive seizures are becoming more frequent, with approaching anuria. It must be used before the case is hopeless to be of value.—*Annales de Gynécologie et d'Obstetrique*, June, 1907.

Book Reviews.

Diseases of Women. A Clinical Guide to Their Diagnosis and Treatment. By George Ernest Herman, M.B. London, F.R.C.P., Consulting Obstetric Physician to the London Hospital; Consulting Physician-Accoucheur to the Tower Hamlets Dispensary; Late President of the Obstetrical Society of London and of the Hunterian Society; Formerly Physician to the General Lying-In Hospital and to the Eastern District of the Royal Maternity Charity, and Examiner in Midwifery to the Universities of London, Oxford, Cambridge, Durham, and the Victoria University, the Royal College of Physicians and the Royal College of Surgeons. Third Edition. New York: William Wood & Co., 1907.

In this new edition the general plan of previous ones has been followed, the author having brought the subject matter thoroughly up to date. The therapeutic indications are given concisely, following the lines of most writers of the present time; in the surgical paragraphs the newest operative methods are fully described. While he shows a preference for hysterectomy in the treatment of carcinoma of the vaginal portion of the cervix, giving a detailed description of Wertheims' operation, he nevertheless discusses the Schroeder amputation of the cervix for this condition, an operation that should be abandoned. While the work is written from a clinical point of view and in previous editions pathology was left to the pathologist, he now inserts a short histological description with cuts, of the more important diseases, such as cancer and chorion-epithelioma. The chapter on the latter affection has been entirely rewritten, bringing it up to the modern conception of this disease. The section on urethral caruncle is well written and contains a new classification. In addition to the changes in the chapters on the various pelvic organs, there are some in the introductory sections, setting forth the common conditions of the nervous system which may cause symptoms referred to the pelvis, neurasthenia and hysteria being described as they present themselves to the gynecologist. As a work for the student and practitioner it has much to recommend it. The maladies are arranged, for example, according to their leading symptom, the one first mentioned by the patient, thus presenting them in a way in which they appear in practice and affording a help in the differentiation of diseases presenting somewhat similar symptoms.

A System of Medicine, by Many Writers. Edited by Thomas Clifford Allbutt, M.A., M.D., LL.D., D.Sc., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge; Fellow of Gonville and Caius College; and Humphrey Davy Rolleston, M.A., M.D., F.R.C.P., Physician to St. George's Hospital and to the Victoria Hospital for Children; Sometime Fellow of St. John's College, Cambridge. Volume II., Part I. London: Macmillan & Co., Limited; New York: The Macmillan Company, 1906.

The second volume of the new edition of Allbutt's System of Medicine appears in two parts of over 1,000 pages each, constituting really two complete volumes. In the first edition there was a curious confusion of volumes, the title-page and the cover often contradicting each other in the number of the volume. The new edition seems to be following in the same uncertain path, and why those two volumes should not be numbered II. and III., instead of Parts 1 and 2 of Vol. II., we cannot understand. This, of course, does not affect the value of the work, but it is confusing to the reader who wishes to consult it. It offends one's sense of order and system, and adds an unnecessary complication to future bibliographical references. However, this is merely a matter of mechanics, and has nothing to do with the capital material contained in the two volumes, or two parts of the one volume.

Part I. deals with the infective diseases and intoxications, continuing the subject begun in Volume I. It opens with a long, but very interesting, article on the General Pathology of Infection, by Prof. James Ritchie, of Oxford. In the former edition this article was written by the late Prof. Kanthack, but so great has been the advances in this branch of medicine in the past decade that the eighty pages found sufficient by the former writer are expanded to two hundred pages in the present edition. We think the author has taken a little more space than his subject really demands in a work of this kind, yet so interestingly does he write that, had we the revision of the article, we should be loath to cut out any considerable portion of it. The treatise is divided into four sections: The Relations of Bacteria to Disease, Changes Produced by Bacteria in the Animal Body, Immunity, and Bacteriology in Relation to Therapeutics. We should like to review this treatise at length, for it deserves a much more extended notice than we are able to give it, and to point out merely the objections which we might bring against certain of the writer's views would be unfair. While not agreeing fully with Prof. Ritchie on certain moot points, we nevertheless do not hesitate to say that nowhere, not even in Metchnikoff's classic treatise, have we read a clearer and better reasoned presentation of the subject of infection than here. The ordinary physician in general practice cannot hope to keep himself *au courant* with the enormous literature on infectious diseases of the present day, and he needs from time to time to read some general review which will put him up to date with this rapidly progressing science. It will take a good deal of his precious time, the fine print will try his eyes somewhat, and he will wish that the writer had possessed or exercised the gift of condensation rather more; nevertheless he will rise from the careful reading of this treatise with the conviction that he knows more than he did of the relation of bacteria to disease; that he knows, in fact, everything essential that there was to know up to the end of 1906.

Following this article are contributions on the infectious diseases, first those of established bacteriology and then those undoubtedly infectious but of doubtful nature, that is to say those the specific germ of which has not yet been isolated. The latter include most of those ordinarily classed among the diseases of childhood and also smallpox, common colds, rheumatic fever, and hydrophobia. The volume closes with a section devoted to intoxications, in which are included food poisoning, grain poisoning, alcoholism, opium and other intoxicants, and metallic and other poisons. Those subjects are treated of quite satisfactorily in a general way, but there is little that is new in the articles or that cannot be found in other treatises on the same subjects. There is a tendency to provincialism in some of the articles which detracts from the encyclopedic character that one expects to find in a composite work of this kind. For example, in the article on typhus fever, in other respects an admirable treatise, nothing is said in the geographical section on the prevalence of this disease in the cities of the Mexican plateau. The disease is endemic in Mexico City and other communities in that country, as travelers have sometimes learned to their cost, and in an encyclopedic treatise, presumably intended for the instruction of all English-speaking physicians, a casual mention of this fact is demanded in the interests of completeness at least. The ignoring of facts easily learned by a study of American medical literature is apparent in some of the other articles. This is perhaps natural in a British work, but it is a fault, and one which detracts from the value of the System for American readers. It is, however, an omission easily corrected by the reader, who does not pin his faith to any one authority. Taken as a whole, this is a work of prime merit and may, to judge from the sections thus far published, be safely commended to the practitioner who seeks for the latest information on matters pertaining to internal medicine.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. June 1, 1907. Philadelphia and New York: Lea Brothers & Company, 1907.

The present volume of Progressive Medicine contains chapters on Hernia, by W. B. Coley; Surgery of the Abdomen, exclusive of Hernia, by E. M. Foote; Gynecology, by J. G. Clark; Diseases of the Blood, Diathetic and Metabolic Diseases, Diseases of the Spleen, Thyroid Gland, and Lymphatic System, by A. Stengel; and Ophthalmology, by E. Jackson. While all the chapters are of value, we would draw special attention to the timely article of more than forty pages on cancer of the uterus, which gives an admirable résumé of recent work on the subject of cancer in general, and also includes criticisms of some of the recently expressed views. This is followed by another important article on fibroid tumors of the uterus. The whole number is of more than ordinary interest, and several of the articles are of permanent value.

Weiterentwicklung der Familiären Verpflegung der Kranksinnigen in Deutschland seit, 1902. Referat erstattet im Auftrage des Zentral-Komittees auf dem Internationalen Psychiatrischen Kongress in Mailand am 26 September, 1906. Von Professor Dr. Konrad Alt, Direktor Landes-Heil- und Pflegeanstalt Uchtspringe (Altmark). Mit 1 Karte und 1 graph. Tabelle. Halle a. S.: Verlag von Carl Marhold, 1907.

This pamphlet briefly illustrates the benefits and great increase in family and colony care of the insane in Germany.

Society Reports.

SIXTH INTERNATIONAL DERMATOLOGICAL CONGRESS.

Held at the Academy of Medicine, New York City, September 9 to 14, 1907.

(Special Report to the MEDICAL R[illegible].)

Monday, September 9—First Day.

THE PRESIDENT, DR. JAMES C. WHITE OF BOSTON, IN THE CHAIR.

PRELIMINARY to the scientific work of the Congress, the following addresses of welcome were delivered:

For the United States Government.—By Surgeon-general P. M. RIXEY, United States Navy, representing President Roosevelt. In his address Dr. Rixey extended a most cordial welcome from the President of the United States, especially to the delegates from foreign countries who had honored us by their presence, and he expressed the hope that the occasion would be the means of forming many ties that might be mutually beneficial. The coming together of such bodies of men, experts in learning and specialists in the great field of dermatology, could not but be productive of much good to suffering humanity, not only of this but of every country here represented. During the past twenty years the subject of skin diseases had, in common with other medical branches, received a great impetus. The introduction of laboratory methods had opened up a world of useful information, and especially to those in the Government services the period had been one of constant advance and discovery, brought about particularly by our advent into tropical and heretofore little known countries. So important had the subject become that we were now bending our efforts to perfect the members of the medical corps of the services in the knowledge of this specialty, and to equip them for practical and research work in all parts of the world. Dr. Rixey said he was particularly pleased to learn that this Congress had taken active steps to demand from educational institutions more careful consideration of the study of diseases of the skin. In his naval medical work he had found upon investigation that the proportion of dermatological diseases to all others was about 13 per cent. This showed clearly how important the subject was, and in the post-graduate medical school of the U. S. Navy at Washington more and more attention was being given to skin troubles, both in the didactic teaching and in the laboratory, and many of their most interesting reports to-day were on that subject, especially in connection with tropical medicine.

For American Universities.—President IRA REMSEN of Johns Hopkins University, in his remarks, said he esteemed it a great honor to be permitted to appear before this Congress and express a welcome on behalf of the universities of this country, especially to those members who had come from foreign countries, and he sincerely hoped that the work of the Congress might in every respect prove profitable and pleasant. The reason for the existence of this Congress was research. The members had come together to discuss the results of their own researches and those of their coworkers. The universities were the training grounds of research. This fact had come to be recognized in medical circles in this country, and there was at present a well-defined university movement among the medical schools. Not many years ago the relation between the medical school and the university was largely nominal. During the past quarter century, however, this university movement had acquired a great momentum. The universities were taking possession of the medical schools, and the latter were trying to get under cover of the universities, although the speaker said he was afraid that there would not be enough universities to go around. What were the advantages of such a university connection? By the leaders in the movement it was clearly recognized that the atmosphere of research was the best atmosphere for teaching, and that he took to be the fundamental point in connection with this university movement. Another reason why the medical schools were coming under the university banner was this: In the olden times the medical school was a profitable business, but that day had gone or certainly was going by, and the fact had become apparent that it was very expensive to properly conduct a medical school. It required money and it required endowments, and none could hope to survive without the latter. The medical schools and the medical departments of universities were now on the same footing, as were other branches of higher education. The old-fashioned medical school could not hope for any endowment in the ordinary course of events, whereas the universities had been fortunate enough to receive them. These were two reasons why the relationship between the medical schools and the universities was becoming closer and closer.

For the Medical Profession of the United States.—Dr. JOSEPH D. BRYANT, president of the American Medical Association, said the members of the American Medical Association were always glad to extend a cordial fraternal welcome to all those who labored for the advancement of medical attainment and for the relief of human affliction. To the branch of the profession which the Congress so fittingly represented belonged infinite praise and profound congratulation because of the eminent success which had attended its efforts in a difficult and often perplexing field of activity. The members of the American Medical Association extended to those of other lands and of their own a most cordial greeting. They bespoke the earnest consideration of the Congress of the plans and purposes of the American Medical Association, and invited its encouragement and cooperation, so that in the near future the medical profession of the world might act with conspicuous harmony in all matters making for the health, the contentment, and the security of the people.

Address by the President of the Congress.—Dr. JAMES C. WHITE of Boston, after extending a cordial welcome to the Congress, gave a brief sketch of some of the changes which had taken place in the study and practice of dermatology during the past half century, and uttered a word of caution regarding the unnecessary division of diseases and the multiplication of titles. Many, he said, were inclined to magnify the significance of slight clinical variations, to attribute to them specific importance, and to emphasize their pseudo-independence by bestowing upon them individual titles. Well-established landmarks in dermatology should not be changed excepting for reasons founded on demonstrable differences in anatomy and etiology. He believed in the creation of a standing committee of the Congress to consider the subject in a broad way, composed of members from different parts of the world, and unprejudiced by past systems of schools or individuals. Among the important questions for them to act upon he suggested the following: 1. What were the influences of race, geographical conditions, climate, national customs, etc., upon the evolution and type of diseases of the skin? 2. What variations did emigration induce in dermatoses? 3. What cutaneous affections should national governments regard as infective and seek to control by restriction of immigration, enforced isolation, and similar measures? 4. How far was it possible and incumbent upon national governments to control the continuance and prevalence of hereditary dermatoses by restrictions upon marriage laws? 5. Should not the influence of this body be directed to induce governments to aid in the support of researches bearing upon sanitary questions of national importance?

Dr. White said we must all be greatly interested in the investigations recently carried on by our colleagues in certain tropical regions, which were of vast importance to derma-

tology and general medicine. Looking backward over his fifty years of study and practice in affections of the skin, he recognized three distinct eras or advance: 1. The knowledge founded on a more careful study of the external manifestations and unbiased interpretations of clinical phenomena. 2. A deeper knowledge of the minute anatomy of tissue changes in, and a more scientific grouping of dermatoses. 3. The recognition of the real nature and cause of visible lesions and the essence of disease—a true system of pathology, as well as the promise of attainment of the power of prevention, of establishing immunity, and of founding a broader system of rational therapeutics. Noteworthy progress, especially in research work, had been made since the last meeting of the Congress in Berlin. The discovery of the *Spirochæta pallida*, its etiological relations to syphilis, and its revolutionary bearings upon the pathology of that disease had stimulated the production of numerous articles from observers in all parts of the world. Their committee of organization had selected as themes for special consideration at this meeting such subjects as would enable the distinguished workers in these fields of research to present the results of their latest investigations and conclusions.

(To be continued.)

BRITISH MEDICAL ASSOCIATION.

Seventy-fifth Annual Meeting, Held at Exeter, July 27 to August 2, 1907.

(Special Report to the MEDICAL RECORD.)

SECTION OF TROPICAL DISEASES.

Wednesday, July 31—First Day.

The Best Methods of Carrying Out Antimalarial Sanitation, with Special Reference to Such Plans as May Be Most Suitable for Populations in the More Primitive Stages of Civilization.—Profession SIMPSON, King's College, London, opened the discussion on this subject. He said that the change in ideas concerning the causes and prevalence of malaria which had come about in consequence of the work of Laveran, Manson, and Ross, together with the progress which had been made in the practical applications of Ross's discovery, rendered a discussion on the prevention of malaria a much easier and more practical undertaking than formerly. The vagueness attending former discussions was not because of doubts being entertained as to the beneficial results following in certain instances the clearing, draining, and reclaiming of low-lying lands, but it was due to the inadequacy of the miasma theory to explain satisfactorily the prevalence of malaria when there were no marshes or forests and when the drainage of the land appeared to be good. Similarly the personal protective measures based on the theory were found to be far from being uniformly successful. Fortunately the vagueness and obscurity were now cleared up. The facts established that the malarial parasite had a life cycle in man and in certain genera of mosquitos, that such mosquitos were the carriers of infection, and that water was required in the breeding places of the mosquitos for their larval development explained the value and the limitations of clearing, draining, and reclamation, and explained the value of the mosquito curtain as a protective against malaria, which had been formerly vaguely suspected. The first step to be taken in a malarious district was to localize those parts that were malarious and those that were not. For this we had two methods: The examination of the children to localize the area of malaria prevalence and the searching for the malaria-bearing mosquitos to focus or discover the particular source or sources in that area from which the malaria was derived. The differentiation of mosquitos was of no practical value, because very few persons had the knowledge whereby they could discriminate between an anopheles that is malaria-bearing and one that is not. For preventive purposes the campaign should be directed against all mosquitos and their breeding places in the vicinity. Unnecessary expense was always to be avoided, therefore it was essential that while protecting the community, operations should not be extended further than would meet this requirement. The distance depended a good deal on local conditions. As a rule the anopheles did not fly far from its breeding grounds. Could it not be laid down even in very malarial districts that a distance of a quarter of a mile was a sufficiently protective zone? Port Swettenham, in the Malay States, was formerly so malarious as to raise proposals for its abandonment. Now it had been rendered free from malaria, though situated less than a quarter of a mile from marshes containing anopheles. Protective measures against encroachments of the sea and against the overflowing of rivers as well as the drainage of great marshes were costly and demanded the mechanical skill of highly trained engineers well versed in the drainage and reclamation of land. When such conditions existed, removable only by the execution of large works, the community was best protected by the safeguards adopted in the Roman Campagna, viz., by mosquito-protected houses, mosquito curtains, the destruction of breeding places in and around the immediate premises, veils and gloves in the evening, and quinine as a prophylactic in the unhealthy season. Precautionary measures of this kind would not be taken by more than a few, unless, as in Italy, there was a medical staff with authority to visit the houses systematically once a week during the malarial season. Even under the most unpromising circumstances simple measures adopted with the object of preventing tidal waters overflowing to the low lying land close to the town, and the draining of this low lying land in order to lower the subsoil water and give a free outlet to rain water, brought about excellent results. Port Swettenham had been freed from malaria by the construction of a bund in such a situation as to prevent the tidal waters from the marsh overflowing onto the low land close to the town, which formed a part of the marsh, by clearing this low-lying land and draining it by a series of parallel ditches with small wooden sluices at their outlets through the bund, and by filling such portions of low land as could not be drained. The success achieved at Port Swettenham showed that no place with similar conditions, however malarious, should be considered to be beyond remedial measures. Backwater and other pools found in many rivers during certain seasons of the year or in waterways in the plains or on the sides of the hills were not uncommon agents causing malaria in a district. Very little work with a few coolies could, by the cutting of channels into the main streams and by running many of them together, remove the stagnancy of their waters or at least remove the pools to a safe distance. If any pools could not be removed by the method of draining them, they could be regularly treated with kerosene or petroleum. The training of Nullahs together with other antimalarial measures had been followed by very excellent results in Hong Kong, where the admission to hospital for malaria had been reduced more than half during the past two years.

Turning to artificial conditions as distinguished from natural conditions favoring malaria prevalence, those caused by excavation works, railway embankments, and buildings were, the speaker said, well known. It was extraordinary to see the amount of damage to the health of a locality an engineer or contractor would do, because no one had the courage to insist, in the agreement drawn up for the execution of the works, that the place should not be made malarious by them. Wherever one went in any part of the world the same mistakes were seen and the same preventable conditions were reproduced. The sanitarian's advice was sought only when the locality had become notoriously unhealthy, and then sanitary works to remedy what could have been prevented were set down as very costly. For preventive purposes advice should be asked before the works were begun. It was more valuable

then, and would save an immense amount of sickness and expense. None but the Americans had hitherto proceeded on these lines.

Prof. Hans Ziemann, Surgeon-Major, German Navy, and Medical Adviser in the Cameroons, W. Africa, read a paper on "Malaria Prevention in Uncultivated Districts." He said we could combat malaria (1) by destroying the malaria parasite in man, (*a*) administering quinine systematically to those infected with malaria, (*b*) killing the malaria parasites as soon as they invade the body at the very beginning of their development and before any manifestations of fever; (2) by destroying the malaria-bearing mósquitos; (3) by protecting man against the bite of malaria-bearing mosquitos; (4) by increasing the resisting powers of the body and by teaching the nature and causes of malaria. These measures were based on the assumption that the development of the malaria parasites took place only in man and the mosquitos. This might be accepted in a general way, since all the blood protozoa hitherto found in the lower animals, though very similar to that of man, were nevertheless quite distinct. Schaudinn had suggested the possibility of the hereditary transmission of the malaria germs to the progeny of malaria-infected mosquitos, but so far all endeavors to prove the presence of malarial parasites in the ova of malaria-infected mosquitos had been unsuccessful. The stamping out of malaria by the systematic administration of quinine to an entire population, as advocated by Koch, might be possible on some small island under the constant supervision of a large official body, but was impracticable in large districts with a fluctuating population, as in West Africa. On this point the speaker was at one with all English authors. On the other hand, the true quinine prophylaxis, namely the administration of quinine with a view to prevent from the very outset the development of such parasites as might have invaded the body, was certainly efficacious, provided, of course, the drug were easily soluble and the intestine able to absorb it. The prophylactic dose of quinine should as far as possible correspond with the therapeutic dose, and the drug should be constantly circulating in the blood. The therapeutic dose was 1 gram for an adult, and the drug was excreted in about four days. Therefore 1 gram of quinine should be taken every four days, preferably in the evening before going to bed, with 5 minims of hydrochloric acid in a glass of water, and on the appearance of ringing in the ears and other nervous troubles, with 1 gram of potassium bromide. If quinine was not tolerated, it should be substituted by an equal dose of euquinine. In case of intolerance to 1 gram of euquinine half a gram of quinine or half a gram of euquinine might be tried. Those who could not take half a gram of euquinine had better not go to the tropics. Not to forget the quinine days, the drug should be taken on the 1st, 4th, 8th, 12th, etc., viz., on dates divisible by 4 up to the 28th day of the month, to commence once more with the first day of the following month. A few years ago the Cameroons were a place of terror and death to the European. Thanks to quinine prophylaxis, the mortality from malaria, which stood at about 8 or 9 per cent., had gradually fallen to zero. The destruction of malaria bearing mosquitos in uncultivated districts was best achieved by killing the larvæ and nymphæ. This method had given splendid results in the British Colonies. In the Cameroons it had reduced the number of malaria-infected natives by at least one half. In places where the swamps were so vast that it was impossible to combat the mosquitos, no further European colonization should be attempted.

Further systematic efforts should be made in propagating such plants as the American pondweed (*Anacharis alsinastrum*), which covered the surface of the water and thus suffocated the larvæ and nymphæ of anopheles. In North Germany the rapid decrease of malaria in the neighborhood of Wilhelmshaven was to be associated chronologically with the propagation of this water pest. The protection of man against the bites of anopheles was best attained by the use of mosquito-proof houses. Ointments and oils supposed to prevent mosquito bites might help for a few hours, but were of no practical value. Europeans should reside at a distance of no less than three-quarters of a kilometer (about half a mile) from the habitations of the malaria-infected natives. The excellent results obtained by such a measure in Old Calabar, in Akkra, and in the Cameroons were well known. General hygienic measures were of the utmost importance. In all malarial countries, even in the malarial districts of Germany, it was known that the poor population contributed the largest contingent to the infection. In Africa the population best fed, best clothed, and best housed was also the best protected against malaria.

The influence of the physician in the tropics should become far greater than it had hitherto been, for most government measures were closely connected with hygienic necessities. Men like Balley and MacGregor had shown the possibilities, in hygienic respects, of a broadminded administration in Africa.

Surgeon-Major Nott, I.M.S., described an interesting experiment in anti-malarial sanitation carried out in 1905 in the town of Berhampur, in deltaic Bengal. The measures taken were those of superficial drainage of collections of water, removal of jungle, and repeated application of kerosene oil. As expected, there was no means of forming an opinion whether malaria was lessened, comparison with previous years being fallacious. But success certainly attended the efforts, and showed that the breeding of anopheles could be checked by measures of a modest character as regards organization and cost.

Dr. W. J. Prout, C.M.G., said it was not wise to entrust the carrying out of sanitary measures to local town councils or local boards on which the majority was native. Instances could be given where this had resulted in an absolute stoppage of sanitary progress. Sanitary administration should be kept in the hands of the government. Education was important so far as the children were concerned. It was useless to attempt to convince the adult native, he was too conservative and too fatalistic, but the negro child had shown himself extremely susceptible to education, and assimilated hygienic teaching with avidity. As an anti-malarial measure, the importance of the administration of quinine to native children had not been sufficiently realized. Dr. Prout strongly advocated the free distribution of quinine among the natives. He agreed with Professor Ziemann as to the necessity of placing more power in the hands of medical men.

Dr. Louis W. Sambon said that the knowledge so far acquired on the etiology and epidemiology of malaria had led to the adoption of very valuable prophylactic measures. The very definite information we now possessed concerning the agency of the mosquito in the propagation of the infection had enabled us to apply vigorously and judiciously the old preventive measures against this dangerous insect pest: Cotton or wire netting to prevent its stab; drainage, cultivation, forestry, and the use of kerosene oil to reduce its prevalence. We had moreover extended the use of quinine with the object of exhausting the supply of parasites. But all these measures were necessarily limited in their application, and therefore only of temporary or individual value. Although they had been in use from time immemorial, the struggle between man and malaria was now as fierce as ever. It had been going on since the days of Empedocles, and certainly began long before the draining of the Selinuntine marshes. Anti-malarial sanitation appeared to be as hopeless as the work of the Danaides, condemned to fill bottomless vessels. And, indeed, one single shower might upset the most costly drainage works, one small rent might be sufficient to render the mosquito canopy worse than useless, obstinate intolerance might prevent the administration of quinine. To stamp out malaria, we needed further measures.

Continuing, Dr. Sambon said that it was a very great mistake to think that we had learnt all that could be known about malaria. There were many points which still required elucidation, and further knowledge would certainly enable us to work out more efficient means of prevention. We knew that malaria had disappeared spontaneously from many places. It had practically disappeared from the few districts of England; it had disappeared from Holland until about twelve years ago, when it suddenly reappeared. In the deadliest malarial regions of the world we had discovered scattered areas free of the endemic, notwithstanding the great prevalence of the disease all round and the presence of all the necessary favoring conditions, including a profusion of the malaria-bearing species of Anophelinæ. We must endeavor to find out the reason why under natural conditions, and independently of the agency of man, malaria had disappeared from these places. Some years ago the speaker had suggested that the disappearance of the intermittent fevers in places in which the suitable mosquitos abounded was probably brought about by the agency of hyperparasites. He had pointed out that the "black spores" or "brown bodies" discovered by Major Ross, believed at first to represent a special stage in the life-history of the malaria parasite, were hyperparasites belonging to the genus *Nosema*. These organisms attacked the malaria parasite in its oocyst stage and destroyed it within the stomach of the mosquito, just as they destroyed the larvæ of *Filaria immitis* developing within the malpighian tubes of mosquitos. A careful study of the natural enemies, both of mosquitos and of their parasites, would probably enable us to solve in an efficient and economic way the great malarial problem. That the suggestion was quite practical might be gathered from the fact that it was by means of natural enemies that agriculturists had been able to overcome the insect pests most injurious to their crops. No better example could be adduced than that of the Australian lady bird, *Vedalia cardinalis*, with which Dr. Riley had saved the orange industry of California.

Sir Patrick Manson, K.C.M.G., F.R.S., said that whether the spontaneous disappearance of malaria from certain districts was due to hyperparasitism, as suggested by Dr. Sambon, or to some other unknown cause, it certainly was a fact of the greatest importance. It should be thoroughly investigated so that we might be able to reproduce the same conditions elsewhere, and thus eradicate malaria. He agreed with Professor Ziemann that the authorities should give every opportunity to the physician in Tropical colonies to institute such measures as experience had shown to be of service in the control of malaria.

Lieutenant-Colonel G. M. J. Giles, I.M.S., said the work of differentiation of species of Anophelines is of less importance than might be imagined. Speaking generally, where one species would breed, another would. Our knowledge of the harmlessness of most species was very uncertain, and based mostly on negative evidence. For practical purposes we should destroy all possible breeding places within reasonable distance of the area to be protected. The discussion of instances doubtless genuine enough, but exceptional, of migrations of mosquitos was of little practical importance. The reports of the Italian Society for the Study of Malaria were full of such instances. On this account spot maps of incidence of cases in infected towns were of the greatest importance in the work of practical sanitation. He advocated a weekly large dose of quinine rather than daily small doses, which were apt to give rise to chronic cinchonism. Self drugging with quinine was extremely common amongst the white residents in West Africa, and was often pernicious. The best way of preventing puddles was that the authorities should punish severely any waste of water.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twenty-ninth Annual Meeting, Held at Washington, D. C., May 7, 8, and 9, 1907, in Connection with the Seventh Triennial Congress of American Physicians and Surgeons.

(Special Report to the Medical Record.)

Dr. A. W. de Roaldes of New Orleans, La., President.

(*Continued from page 453.*)

Wednesday, May 8—Second Day.

Spasm of the Esophagus.—Dr. John W. Farlow of Boston reported the case of a woman of fifty years who was subject to spasm of the esophagus and whose father and paternal uncle were subject to similar attacks. The patient herself had had a few attacks of discomfort of the throat while eating, and four years ago while eating a piece of raw apple became pale, looked distressed, put her hand to her throat, and was evidently in great discomfort. Pain was felt in the lower part of the neck, but did not extend to the back or arm. She was able to speak, and pulse and breathing were not affected. Was unable to swallow anything during the seizure. Hot applications to the neck gave comfort, but did not relax the spasm. In about twenty minutes she felt relief from pain, raised some frothy mucus which had collected in her throat, and the attack was over. Examination showed only a slight chronic pharyngitis and a moderate enlargement of the lingual tonsil. She then went for a year without a further seizure, and the third attack did not come on for still another year. Massage of the neck was begun, cold compresses used, and local treatment applied to the throat. She had now gone another year without an attack, but the author admitted that treatment might not have had any effect. He would ask what was the nature of such attacks and how they were to be differentiated. Angina pectoris would cause great dyspnea and pain in the chest, radiating down the left arm, and there would be changes in the pulse and breathing. These were all wanting in his patient. Esophageal spasm was more likely to occur in neurotic patients, but this woman was not in the least neurotic. A further matter and the one of practical importance concerned measures of relief. The patient was unwilling to allow the use of any anesthetic which might have caused unconsciousness. A hypodermic of morphine might have relieved her, but in the two attacks in which Dr. Farlow saw her she seemed hopeful that the spasm would soon relax and was loath to have morphine used. As she could not swallow and her mouth was full of saliva and mucus, he did not think that cocaine would have had any effect. Emetine had been suggested in tablet form, and the patient could carry the remedy with her, to be used at the onset of any further attack. Perhaps apomorphine in 1-16 grain dose hypodermically would be efficacious, but as it would require from five to twenty minutes to act, it might not really shorten the attack. Dr. Farlow asked for therapeutic suggestions from those present.

Dr. H. L. Swain of New Haven, Conn., had had a recent case of the kind referred to by Dr. Farlow. His patient referred the origin of his spasm to a point on the left side of the throat. There would be a sort of cramp with pain, and then until the throat relaxed nothing could be swallowed, even water. The sigmoid sinus was cocainized and an instrument passed down to a level just below the cricoid. Then the man was able to swallow. By the esophagoscope a round swelling was discovered on the left side about 25 cm. down from the teeth. A mild silver nitrate solution was applied, but the patient did not report again and his later history was unknown. The condition seemed to be a cramp of the esophagus.

Dr. W. E. Casselberry of Chicago wished that Dr. Farlow had tried cocaine. He had had several cases him-

self similar to the one reported, as to symptoms at least, and in these cocaine had done good service. Even if we are not able to apply the remedy directly to the seat of spasm enough exudes through to near the place of spasm to affect the muscles in the neighborhood.

Dr. L. A. Coffin thought that some of these cases were instances of disordered reflexes. In one case cure had resulted by the removal of adenoids. There might be various peripheral points from which the stimulus would come, it being expended in each case in the esophagus.

Dr. E. Fletcher Ingals of Chicago had had under observation for some weeks a case similar to Dr. Farlow's. The passage of bougies of large size gave relief. Cocaine might be used before passage, though his patient preferred its omission. General tonics and bromides in these cases were an adjuvant to treatment.

Prof. Gustav Killian said it was necessary to exclude changes in other organs before making a diagnosis of local spasm. The latter might be primary or secondary. In one case it came from a diseased stomach. In other cases the patient ate too rapidly and did not masticate sufficiently. He had devised an instrument to illustrate to the patient the effects of insufficient mastication. Such a demonstration had more effect on the patient's mind than any amount of general advice.

The President, Dr. A. W. de Roaldes, wished to call attention to the fact that some of these spasms might be secondary to disease of the nervous system. He had seen the condition in tabes. It might come on not only late in this malady, in which clonic attacks were often noted, but also in the early stages. In one of his patients the esophageal symptoms was the initial evidence of tabes.

Dr. G. Hudson Makuen believed in the existence in many of these cases of a nervous or psychical element. The patients could not swallow because they thought they could not or were afraid they could not. They always did better while under a condition of mental exhilaration. This might arise from the constitutional effect of cocaine when applied rather than to the latter's effect on the spasmodic factor. In one of his own patients there seemed to be a unilateral paresis of the pharyngeal muscles.

Dr. Farlow closed the discussion, stating that while all that had been said was interesting, no one had offered him any suggestions as to treatment of his own case. Exhilaration was not a factor in his own case nor was improper eating. If cocaine was applied when the mouth was full of saliva it would probably fail to act. In his own patient he would feel loath to pass an instrument of any size down the esophagus, especially when the patient was gasping for breath. Methods of treatment which could be used in dispensary patients with frequent attacks could not be used with patients who went a long time between attacks and were in perfectly good health in the meantime. It was worthy of note that the father and uncle of his own patient were affected in the same way, also an aunt and a sister. In this instance there seemed to be some family peculiarity.

Some Considerations Relative to Systemic Infection Through the Tonsillar Ring.—Dr. J. L. Goodale of Boston in this paper referred to one on the same topic read at the meeting in 1906, and stated that during the past year he had continued his work along the same line. He called special attention to the part played by the system in resisting the invasion by microorganisms. A series of cases had come under observation illustrating the possibility of the entrance of rheumatic poison through the tonsils. Removal of the latter had generally been followed by improvement but in one case a complication of joint symptoms was observed in association with throat symptoms. A detailed history was given of the case. The faucial tonsils were of all points in the tonsillar ring, the vulnerable point, but even after they had been removed infection might occur through the lymphoid structures of the posterior pharyngeal wall. Tuberculous infection might occur through normal mucous membrane without leaving any discoverable trace. In some of the obstinate cases in which infection seemed to follow with as great frequency after operation as before it, it seemed probable that the cause of frequent bacterial invasion was not attributable as much to a faulty distribution of lymphoid elements as to a predisposition to such infection on the part of the patient himself. Finally we must further study the part played by the host in such cases. When one was called to such a case as had been considered one should consider not alone the alterations in the tonsils, but evidences of lymphoid change in the vicinity. Even if the tissues appeared normal one could not say that they might not have been in time past channels of entrance for microorganisms. If the individual in his previous attacks of systemic disease had had coincident disturbances in the throat this fact became of great importance. If it was possible to test the opsonic index of the individual with reference to the germs suspected of etiological relation which had been recovered from the throat confirmatory evidence would thereby be obtained.

Dr. W. E. Casselberry called attention to the chain of lymphatic follicles behind the posterior faucial pillars, inflammation of which was called pharyngitis lateralis. This participated in the usual inflammations of the pharyngeal lymphoid tissues. In his opinion it was responsible for some of the systemic infections as rheumatism, endocarditis, etc. Such glands might be destroyed by the cautery. They often kept up trouble after the tonsils proper had been removed, and it was often necessary to extend the cauterization up beyond the level of the velum palati and down into the pharynx.

Dr. Robert C. Myles of New York said that the tonsil projecting into the throat was the one to which most attention had been paid, but there were other kinds which were just as dangerous. The crypts went down deep and there the chief sepsis occurred on account of the moderate amount of epithelium. By properly examining the cervical glands one could tell the pathology of the tonsils without looking at the throat. If the tonsil affection was very definite the glands would be hard. In proportion to their softness the infection was likely to disappear. Twenty per cent. of tonsillar affections were of this variety, while eighty per cent. were of the palatal tonsil. Some of these tonsils to which he referred were incapable of extirpation, which was a serious matter. Such tonsils might extend three-quarters of an inch into the palate. There was danger in operating of setting up cellulitis of the neck. The best course was to clean such a tonsil out and involute it. A certain amount of cervical adenitis might result from the salpingeal folds and they should not be overlooked. Adenoids might cause swelling of the glands in the postcervical region. No consideration of any tonsil case was complete which ignored the amount of adenitis present. It was difficult to say how often such glands were tuberculous.

Dr. George L. Richards of Fall River, Mass., had seen cases with periodical attacks of tonsillitis in which it was difficult in the intervals to note any excess of lymphoid tissue, even on separating the palatal folds. In regard to the nature of the glandular inflammation he had found it at times tuberculous and at other times not. Often a tonsillectomy should be followed by enucleation of the cervical glands.

Dr. Francke H. Bosworth of New York said that it was our duty to remove diseased lymphatics. Enlarged lymphatics did not necessarily call for removal. If we removed the mechanical condition in the pharynx, destroying the focus that entangled the germs, we did all we were called on to do. It was not our duty to dig out all the lymphoid tissue, but to remove the pockets which were the source of the mischief. Invagination of the tonsil was a diseased condition, but unless there were pockets the condition was not one of disease. The so-

called palatal tonsil he did not believe to be an organ of the normal body. A large rounded tonsil projecting into the throat without any follicles did no harm.

Dr. F. C. Cobb said that the pathological retention by pockets or anything else tending to obstruct the flow from the tonsils would cause more disturbance than a mere inflammation of the tonsil or of the lymphoid tissue. The latter might be a normal protective. At times it was overcome by the invading organisms which gained access to the general circulation. It was a mistake to obliterate normal tissue simply on the evidence that through it pathological germs occasionally gained access to the system. There was very little sepsis in acute tonsillitis. The tonsil took care of an enormous number of bacteria.

Dr. Emil Mayer called attention to a recent article by Jacobi, taking an entirely different standpoint from that of the theory that there was a direct infection beginning with the lymphatics of the throat.

Dr. Reginald H. Fitz of Boston, President of the Triennial Congress, was invited to participate in the discussion and said that rheumatism was the disease which most interested the general practitioner so far as the present topic was concerned. Whatever the tonsil might do in some infections, it did not do the same in all. Certain peculiarities of one microorganism might allow it to pass through the tonsil, but perhaps this was not true of all microorganisms. He did not know whether the result of tonsil extirpation had been determined with regard to its bearing on cases of multiple arthritis. Infections occurring after removal of the tonsils should be investigated in relation to those occurring before operation.

Dr. Myles said that he did not advocate removal of lymphatics when they were protective, but only when they were suppurating.

Dr. J. N. Mackenzie of Baltimore referred to some of the former theories as to the function of the tonsil. The lust for tonsil operations had now reached its zenith. The laity had become infected with the zeal for removal. He thought that the matter of infection through the tonsils had been very much exaggerated. Dr. Goodale had beautifully pointed out the bacteriological side of the question, but there was another side—the clinical. He was inclined to think that the modern total tonsillectomy was absolutely unnecessary and sometimes harmful. One should be guided in each case coming under observation by safe and sane conservatism and common sense.

Dr. Bosworth referred to his statement made in London twenty-seven years ago that there were no tonsils in a healthy throat and believed that the truth of this statement would soon be accepted by all practitioners. The tonsil described by anatomists represented a disease process.

Prof. Gustav Killian gave a demonstration of various new instruments devised by him for use in bronchoscopy and esophagoscopy and a general discussion ensued on these operations.

Dr. H. P. Mosher was delighted to have had the opportunity of seeing these new devices. He preferred to have the light on the end of the tube so as to get it as near the foreign body as possible. He had noted that Prof. Killian had had to put the suction tube inside the main tube so as to remove the mucus. With the plain, straight solid tube with a light at the end and a smaller tube set into the side of this tube to remove the mucus it was not necessary to introduce a special tube for this purpose. It was of great importance to know how many cases required an emergency tracheotomy after the manipulation and passing the tubes through the cords. Such a thing had been called for in this country and he would like to know of the experience in this respect in Germany.

Dr. E. Fletcher Ingals said that in his practice he found it better to have the light at whichever end gave the most satisfaction. The light at the distal end did not always work well, no matter how bright it was. He preferred a suction tube that could be introduced through the main tube, as we needed all the room we could get, the larger the tube the better also the lighting.

Dr. Emil Mayer said that very frequently blood would show itself on the mirror, obscuring the view. The holding of the light in the hand in the instrument shown was a great advantage. He thought it useless to practice on the cadaver. It was much better to work on the living dog. An injection of morphine kept the animal quiet. One then had conditions approaching clinical practice, viz., the hot air in the face, the mucus, and the little blood.

Prof. Killian, in closing the discussion, said that the diameter of an electric lamp must be at least three millimeters and that the mirror in the tubes would, in such cases, obstruct most of them. He had found records of 116 cases of tracheotomy after bronchoscopy. In these cases the extraction was difficult and it was necessary to have the tube in position a long time. Personally he had never had such a case. If it was not possible to remove the foreign body through the larynx, we had to do a tracheotomy and also a lower bronchoscopy.

Modern Procedures in Excision of Intrinsic Malignant Growths of the Larynx.—Dr. J. Solis-Cohen of Philadelphia presented this paper. He said that modern procedures virtually excluded all endolaryngeal methods. This procedure comprised a central division of the thyroid cartilage and sometimes of the cricothyroid membrane, cricoid cartilage, or even of the trachea, as may be requisite to expose fully the morbid mass and its immediate surroundings when the wings of the thyroid cartilage were separated with retractors or with stout loop ligatures. He regarded preliminary tracheotomy as not requisite except when strong indication existed for precautionary use of a tube after operation. The whole might be done under either local or general anesthesia, the choice being dependent in great measure on the location and apparent extent of the neoplasm and in part on the predilection of the operator. The author then described in detail the steps of the modern operation. He preferred to follow his own method of beginning with an ordinary tracheotomy and, after introduction of the cannula, to incise the skin only so far as to uncover the larynx, thus leaving a broad bridge of skin above the cannula. This lessened considerably the dimensions of the external wound and favored reunion in the sequence. The bridge could be sacrificed if necessary. In his own practice no stitches were taken in the skin wound. Instead a longitudinal strip of perforated plaster was placed along each side of the neck an inch from the line of incision and then this plaster was sutured in several places along the line of thyrotomic incision through the perforations and tied only so tight as to bring the severed edges of the skin to gentle apposition and leave the wound free for easy and immediate inspection. No threads were passed over the line of tracheal incision, which was left bare to favor expulsion of matters from the air passages. A pad of gauze was moistened in bichloride solution, while a broad strip of antiseptic gauze was doubled over a narrow strip of adhesive plaster and secured to the neck, so that the gauze hung down over the dressing upon the seat of the wound. Postoperative treatment was most important, and a skilled assistant should be on hand for the first twenty-four hours. Should it become necessary to reintroduce the cannula into the trachea for any length of time the atmosphere near the head of the bed must be moistened so as to prevent desiccation of secretion. The author paid a generous tribute to the recent work of Semon and Butlin. Dr. Cohen's chief points of variance from the usual methods were the retention of the skin bridge above referred to, the removal of the growth *en masse* upon a plate of excised perichondrium and superjacent tissue, dressing with compound tincture of benzoin, avoidance of sutures in the cartilage and skin, and the special method of loosely approximating the edges of the

incisions. The tincture of benzoin was mopped thoroughly on the raw surface left after removal.

Non-Recurrent Carcinoma of the Larynx, Removed Through the Natural Passages. Dr E. Fletcher Ingals of Chicago reported this case. The patient was a man of forty-four years, laborer, who came under observation in January, 1906, complaining of hoarseness of six years' duration. For the last three weeks he had felt some pain in the region of the left half of the hyoid bone, none previously. Had had also a recent catarrhal cold. There was no dyspnea, but he could not talk, as a rule, much above a whisper. Had formerly been a mild smoker. Had lost a pound or two and had a slight hacking cough. A pinkish gray tumor involved the anterior five-sixths of the left vocal cord, filling the ventricular opening and considerably obstructing the glottis, crowding outward into the ventricular band. The growth had the appearance of malignancy, but owing to its long duration the author hoped it was only papillomatous. The greater part of it was removed at the first sitting. Three days later more fragments were removed, and there was considerable pain felt by the patient in the larynx in the subsequent days. The patient was not seen again for a week and in the meantime the microscopist had reported that the neoplasm was a slowly growing carcinoma with growth toward the surface and considerable keratohyaline transformation of the epithelial cells. At this time Dr. Ingals found a growth at the anterior end of the left cord larger than at the last visit, and this was thoroughly removed with a Mackenzie forceps. After removal of this a growth of about the same size was seen just below the cord and it was also removed. When the patient returned four days later he was very hoarse. Sedative measures were instituted and continued for several months. The patient's condition gradually improved, and in two months it was noted that the voice was much clearer. The patient was again seen over a year after the operation and for the last three or four months his voice had been perfectly normal. A slight thickening of the cords was noted, but was referred to a recent cold. Dr. Ingals stated that although interference with malignant laryngeal growths was likely to stimulate their increase, it appeared to him that when there was doubt as to exact nature and when conditions were such that we had a hope of removing the neoplasm thoroughly by the endolaryngeal method, this latter should be selected. If the examination revealed malignancy and the tumor speedily returned, laryngotomy or laryngectomy should at once be advised if there was reason to believe that a thorough removal could be effected.

Epithelioma of the Larynx; Removal by Thyrotomy; No Recurrence After Three and One-half Years.—Dr. Henry L. Swain of New Haven reported this case, his patient being a clergyman of forty-seven years, who came under observation in March, 1903, with increasing hoarseness dating back several months. The larynx was slightly congested throughout and much swollen on the entire left side, so that no clear view of the true cord could be had. Subsidence of the swelling later revealed a white papillomatous mass growing from the upper aspect of the cord and apparently coming out of the laryngeal ventricle. Nearly the entire cord was covered by the growth. After some thinning of the patient the entire visible mass was removed in small pieces, as it proved very friable. Microscopical evidence was negative. Some two months later the mass returned and was again removed. This was done [illegible] time in the next two months. Six months after the first appearance of the patient it was decided that something more radical must be done. Up to this time no positive evidence of malignancy was manifest under the microscope. Thyrotomy and exsection were then done after the usual modern methods. Recovery was rather slow, but satisfactory. At the present time the patient spoke in a perfectly audible, but rather husky, voice. A fairly good presentment of a vocal band had been produced in the shape of a dense white band where the true cord should be. The false cord was flatter than usual and the ventricle had been obliterated. The reporter laid emphasis on the following points: (1) The ever-present difficulty in coming to a diagnosis; (2) the wisdom, even when in doubt, of operating so as to insure complete removal; (3) the repeated observation of the surprising difference in the appearance of the growth when the larynx was opened; (4) the impossibility of being sure everything malignant had been removed; hence the value of using the Paquelin cautery; (5) the possibility when the larynx was roomy, of shutting up the whole wound instead of leaving the tracheotomy tube in place; (6) the unquestioned advantage of the absolutely recumbent position with the feet raised; (7) the small amount of suffering in an intelligent, brave, and tractable patient as compared with the mercy of a complete cure.

Dr. Ingals saw no reason why cocaine and adrenalin should not be used together in these operations so as to obviate so much mopping. He had had many disagreeable symptoms following cocaine alone. The adrenalin might prevent the absorption of the cocaine and thus prevent constitutional effects. An excess of gum benzoin, say two drams to the ounce, was an advantage, as it made a firmer film over the tissues.

Dr. Thomas Hubbard had observed that in etherized patients adrenalin did not produce ischemia, at least in the nose. He did not know any reason for this. He had not made the same observation with reference to chloroform.

Dr. J. Payson Clark gave the history of a case of laryngeal cancer operated on ten years ago. The patient was still living at seventy and was in good health, with a very firm strong voice. Dr. Gordon King of New Orleans gave a similar case history, his patient being alive and well two years after operation and with good voice.

Dr. R. C. Myles of New York believed that there was something individual in these cases. The cancer might be of the superficial type and a good result follow operation, but he did not believe that cancer of the deeply penetrating type could be cured.

Dr. D. Bryson Delevan of New York reported the history of a case illustrating the fact that the picture as seen in the mirror gave a very misleading idea as to the extent of laryngeal involvement. His patient had been operated on ten years ago and was still in fair condition. Some of the surgeons of the present day were coming to the conclusion that cancer did not admit of cure. The time limit was not to be relied on. It was insufficient to place it at three years, as experience frequently showed. Under the method as presented by Dr. Cohen we were likely to secure the best results. He thought, however, that all methods were hopeless and in the main disappointing. We should continue our investigations in the hope of discovering some cure which would put surgery out of the field entirely.

Dr. J. Payson Clark stated that an operation which would prolong life was often justified even if the case eventually proved fatal. He related the history of one case.

Epithelioma of the Larynx. Dr. Clement F. Theisen of Albany, N. Y., reported this case, which emphasized the necessity of early diagnosis and also the fact that microscopical examination was often difficult and that the laryngologist might lose valuable time owing to the pathologist's uncertainty. The patient was a man of fifty-seven years, with a husky voice for some months. A flat nodular firm growth was seen, involving about two thirds of the left cord. Surrounding parts were reddened. Examination of some small fragments suggested that the condition was merely inflammatory. The reporter's original diagnosis had been carcinoma. Under palliative treatment there was

temporary improvement, but some weeks later it was noted that the whole of the left cord had become involved and there were evidences of encroachment on the right cord also. The diagnosis was now positive, and the dyspnea had become so great that a tracheotomy was done under local anesthesia. After some delay on the patient's part he consented to a radical operation. A total laryngectomy (Gluck) was done three weeks later. Pneumonia proved fatal on the thirteenth day. The microscope showed typical epithelioma. It was worthy of note that the marginal epithelium of the growth was found in a normal condition, but its transformation into malignancy could be definitely seen in the sections. The growth itself was entirely of epithelial origin, and irregular columns of spheres of epithelial cells could be seen growing into the underlying tissues in all directions. In the centers of these areas there was manifest a tendency to rapid degeneration, for the cells were in many places replaced by detritus. The interstitial connective tissue was thickly infiltrated with small mononuclear leucocytes and plasma cells, and in some areas there was proliferation of the small capillaries.

Sarcoma of the Pharynx.—Dr. THEISEN also reported this case. The patient was a girl of eight years with a history of dyspnea for several months. A large mass was seen in the throat, including the soft palate and pushing it forward. The growth extended almost to the epiglottis and apparently involved the nasopharynx. The glands were enlarged on the left side of the neck. It was decided that the case was inoperable and the mixed toxins injections were given. Microscopical examination of a piece of the growth was not decisive. Clinically there was no doubt as to malignancy. Injections directly into the mass were begun and after some time constitutional reaction was noted. Adrenalin injections were not used, as the method was too slow to effect any result in this case. The iodides were also without result. Nothing seemed to make any impression whatever on the growth. Death came from increasing dyspnea about two months after the patient came under observation. The microscope showed spindle-celled carcoma with hyperplasia of adjacent lymph nodes. The reporter referred to similar cases recently recorded in the literature of sarcoma.

(To be continued.)

AMERICAN GYNECOLOGICAL SOCIETY.

Annual Meeting, Held in Washington, D. C., May 7, 8, and 9, 1907.

(Concluded.)

JOINT SESSION WITH THE URINARY SURGEONS.

Surgery of the Kidney.—Dr. GEORGE S. HUNTINGTON of of New York pointed out by means of numerous lantern slides some of the congenital variations of the kidneys and ureters in reference to their development and surgical importance.

Dr. LEWIS GREGORY COLE of New York followed with remarks on the radiographic diagnosis of renal lesions. His talk was accompanied by the projection of numerous lantern slides on the screen.

Dr. CHARLES H. CHETWOOD of New York exhibited specimens, and presented illustrations of renal lithiasis, of pyonephrotic stone kidney, and of renal tuberculosis.

Dr. FRANCIS S. WATSON of Boston presented the subject of calculous anuria, with especial reference to bilateral renal calculus, and to the simultaneous performance of bilateral nephrolithotomy in those cases, and to calculous anuria occurring in patients having but one kidney.

Dr. HOWARD A. KELLY of Baltimore discussed the value and method of mensuration in vesical, ureteral, and renal work.

Dr. GEORGE E. BREWER of New York considered the pathology, diagnosis, and treatment of acute unilateral septic infarcts of the kidney, while Dr. GEORGE M. EDEBOHLS of New York pointed out some of the requirements of up-to-date nephrectomy.

Wednesday, May 9—Third Day.

Cystic Lymphangioma of the Gastrocolic Omentum.—Dr. W. FRANCIS B. WAKEFIELD of San Francisco reported the case of a four-year-old boy, who was brought to Dr. S. J. Hunkin, with an enormously distended abdomen. He presented no other symptoms. For at least two years the child's abdomen had been noticed to be progressively increasing in size. Laparotomy was advised. Dr. Wakefield was invited to operate, and saw the child for the first time on the operating table. Abdominal section disclosed a multiple cystoma larger than an adult head, which was broadly attached to the greater curvature of the stomach, spreading out over a small portion of the anterior and a greater portion of the posterior wall. Its attachment to the stomach was so firm that it could not be separated therefrom without danger of injury to that viscus, and it was therefore cut away as close as possible to the stomach wall. No gross pathological change could be observed in the wall of the stomach, the cystoma having simply plastered itself over its surface. The leaf of the gastrocolic omentum, which passes from the stomach to the transverse colon, was absent, although the ordinary omental apron spread itself downward from the transverse colon over the small intestines. It seemed clear, then, after the tumor had been delivered through the abdominal incision, and the operator found himself able to look directly down upon the pancreas, that he was dealing with a cystic tumor originating in and displacing the upper reflection of the gastrocolic omentum, and that the tumor early in its career, as it developed between the omental folds, had, by simple contiguity, spread itself over and become attached to a somewhat broad area of the stomach wall. A small cystic mass, about the size of a hen's egg, was found loosely attached to the head of the pancreas, and a still smaller one, about the size of an English walnut, was found attached to the serous coat of the stomach, some distance from the main tumor. The tumor was larger than a man's head, and consisted of a number of variously-sized, thin and clear-walled cyst chambers. The central portion of the neoplasm was occupied by a single cavity which made up the bulk of the cystic mass. Surrounding this central cavity on all sides were numerous smaller cystoid masses ranging in size from that of an orange to that of a pea. The walls of all the cyst chambers were thin, easily ruptured, smooth, shiny, and in general appearance resembled the omentum. The component layers of the cyst walls could not be separated. The inner walls of the cyst cavities were in many places covered by somewhat adherent, gelatinous masses, which to the feel were distinctly granular. The fluid contained within the cavities of the cystoma was clear, straw-colored, neutral in reaction to litmus, and coagulated into a solid mass on heating with a drop of acetic acid. In some of the chambers the fluid was mixed with fine crystals, oily to the touch, and microscopically identical with cholesterin. In others the presence of blood was indicated, macroscopically by imparting a dark color to the fluid, and microscopically by the presence of red cells. The cystic fluid everywhere contained leucocytes. The author gave a detailed report of the histological examination of the walls of the cystoma.

Ectopic Gestation with Special Reference to the Treatment of Tubal Rupture.—Dr. HUNTER ROBB of Cleveland, Ohio, gave a brief review of the course of an ectopic gestation, also of the opinions of various authorities as to the treatment to be adopted in emergencies due to tubal rupture; as the patient rarely died from the hemorrhage, but more often from shock, as a rule it was better not to operate until reaction had taken place. Records of several cases treated in this way and also of experimental hemorrhages produced by cutting the ovarian and uterine arteries in bitches were given.

Incision of the Anterior Uterine Wall as the Treatment of Chronic Inversion of the Uterus.—Dr. REUBEN PETERSON of Ann Arbor, Michigan, said that all efforts at reposition of a chronically inverted uterus must be directed towards dilating and incising the unyielding cervical ring. Pressure methods were relegated to the past. Proper treatment was operative from the start. The constricted cervical ring could be incised from above or below. The abdominal route was no easier and did not give as good results as the incision from below. The uterine wall might be incised anteriorly or posteriorly. The former was preferable. He cited a case of twelve years' standing which was successfully treated by this method, and described in detail the operative technique.

Dr. I. S. STONE of Washington, D. C., presented a study of the uterosacral ligaments from the standpoint of their utility as uterine supports.

Post-Operative Inversion of the Vagina; a Presumably New Operation for Its Cure.—Dr. PHILANDER A. HARRIS of Paterson, N. J., said that access to the field of operation was made through a suprapubic median line abdominal incision. The round ligaments were sought and dissected from their imbedments. The vagina was pushed well upward with a staff. A small hole was cut in the vagina upon its right side, and another opposite upon its left. The mucous membrane of the fundus of the vagina between and about these penetrations was curetted. The right ligament was drawn through the apertures near the top of the vagina from right to left. The left ligament was then drawn through the apertures of the vagina from left to right. The distal end of each ligament was then drawn taut, and sewed as high as possible with catgut to the larger portion of its fellow. After sewing the distal portion of each ligament to the proximal portion of the other ligament, the through-and-through sewing was continued at the fundus of the vagina in such a manner as to repeatedly penetrate the ligaments which it covered.

Officers.—The following officers were elected: *President*, Dr. J. Montgomery Baldy of Philadelphia, Pa.; *Vice-Presidents*, Dr. I. S. Stone of Washington, D. C., and Dr. Malcolm McLean of New York; *Treasurer*, Dr. Chas. P. Noble of Philadelphia, Pa.; *Secretary*, Dr. J. Riddle Goffe of New York; *Member of the Council*, Dr. Clement Cleveland of New York.

Philadelphia was selected as the place for holding the next annual meeting, in 1908.

Rectal Alimentation.—Francis B. Boyd and Jean Robertson, from their observations, conclude that proteid food, even when predigested and with salt added, is very poorly absorbed in rectal feeding; the albumin of eggs, as generally used in rectal feeding, is a very expensive and unsatisfactory food stuff; there is no relation in the amount of proteid injected and the amount absorbed, absorption seeming to depend more upon the patient's individual capacity for absorption than upon the amount of proteid food given. The writers declare that fat absorption seems to play an important rôle as a nitrogen saver. The loss of tissue nitrogen in six of their observations is very much larger in those in which the fat absorption is poor. Taken as a whole, these observations show that emulsified fat is a very useful ingredient in rectal enemata, and is far better absorbed than is generally believed. The observations of these observers tend to show that the amount of sugar lost by bacterial action is small, being always below 1 per cent. Excepting Reach's observations, which they do not accept as conclusive, the observers to the use of sugar as not being utilized, but as being split up before absorption, are wholly theoretical. In none of their cases was there any bowel irritation due to the dextrose, nor did alimentary glycosuria occur. They believe that the best results in rectal feeding will be obtained from the carbohydrates and fats. A syringe should never be used for nutrient enemata, but the enema should be very slowly syphoned in by means of a soft rubber catheter and a small-sized filter funnel. These writers conclude that rectal alimentation has a far more limited field of usefulness in clinical medicine than is at present accepted.—*The Scottish Medical and Surgical Journal*

OBESITY, GOUT, AND DIABETES MELLITUS CONSIDERED AS DISEASES OF CELL METABOLISM TRANSMISSIBLE BY INHERITANCE.

BY PROFESSOR WILHELM EBSTEIN, M.D.
GÖTTINGEN, GERMANY.

FROM the many ways in which the so-called disease of metabolism are grouped and arranged into nosological systems by the different authors, it is evident how much at variance are the views of physicians concerning the nature and essence of these diseases. They are often identified with the pathological conditions that go under the name of constitutional diseases, and the term "diseases of nutrition" is often substituted for either one of these names. The latter is the case in the large and well known "Handbook" of Charcot, Bouchard, and Brissaud, in the first volume of which (Paris, 1891) Le Gendre treats of the disturbances (*troubles*) of nutrition separately from the diseases (*maladies*) thereof. Among the disturbances of nutrition Le Gendre considers in the first place the morbid predispositions or diatheses characterized by retardation of nutrition, counting among them the gouty and the scrofulous diatheses, and in the second place the modifications and disturbances of nutrition in pathological conditions. The primary diseases of nutrition, on the other hand, are divided by Le Gendre into the seven groups that follow: 1. The acid dyscrasias (rickets and osteomalacia). 2. The lipogenic dyscrasias (fat formation, the seborrheas, and obesity). 3. Formation of gallstones (the precipitation of cholesterin). 4. Urinary gravel. 5. Diabetes mellitus, from which are distinguished the various forms of pseudodiabetes, viz. diabetes with the excretion of inosite, that with an increased excretion of urea (azoturia), and finally the pseudodiabetes characterized by the excretion of salines (phosphatic diabetes). Gout belongs to the sixth group and is divided into acute and chronic gout and the form due to lead poisoning; while the seventh group contains chronic progressive rheumatism (arthritis deformans).

William Osler, in the third edition of his "Principles and Practice of Medicine," 1898, considers certain forms of rheumatism (arthritis deformans, chronic, and muscular rheumatism), diabetes insipidus, and rickets among the constitutional diseases, in addition to gout, diabetes mellitus, and obesity.

To me it has seemed necessary to place obesity, gout, and diabetes mellitus into one group and to term it hereditary diseases of cell metabolism.* This term appears to me to have quite a number of advantages over the name, "diseases of metabolism in the narrower sense," selected by Leube, but it is not necessary to discuss this latter term proposed by him in the year 1896, because he himself dropped it in the second volume of his "Diagnosis of Internal Diseases," sixth edition; there he groups almost the same diseases as Osler under the heading of the diseases of metabolism, and arranges them together with the diseases of the blood in a still larger division, that of constitutional diseases; Osler, on the other hand, groups the diseases of the blood with those of the so-called blood glands (ductless glands) and considers them separately from both the diseases of metabolism and the constitutional diseases. To Leube diseases of metabolism is the narrower conception, while constitutional diseases is the wider term; in my opinion just the opposite is the truth. Anomalies of metabolism are certainly not absent in any severer forms of disease whatever, for the term metabolism means nothing more than the changes which are observed in the human or animal body, and which are caused by the introduction and removal of the chemical products of exchange; in febrile conditions, for instance, we never miss the disturbances caused by the exaggerated exchange processes of the living tissue. The conception of constitutional disease, in so far as it may be at all allowed, is to be applied to a disturbance caused by the anomaly of the fluids of the whole body, the word "constitution" in exact definition meaning a fixed condition of the body or of its fluids. Such humoropathological conception belongs to a past epoch, and in any case the word "constitutional disease" ought to be completely banished, because not the constitution as a bodily condition may become diseased, but the individual who happens to be the owner of a certain sum of body qualities.

There are many reasons that would seem to justify the separation of obesity, gout, and diabetes mellitus from the other diseases of metabolism and the grouping of them into a separate class of diseases; while the considerations that follow ought to show that the term "hereditary diseases of metabolism" is the correct one for such a group. The close relation of these three diseases is evident from the fact that two of them are quite frequently found in the same individual, while occasionally this is the case with all three; this simultaneous occurrence has certainly been observed too often to be considered accidental, and indeed, so far as I know, the latter view has never been maintained. Nor is transmissibility by inheritance an any less generally acknowledged property of these diseases, which term of course means not the necessity of such transmission, but only a possibility thereof. In any case this transmission occurs so often that here also the possibility of a frequent accident as an explanation seems completely excluded; such transmission, moreover, often extends beyond one, over a whole series of generations.

*Compare my views in Ebstein & Schwalbe, "Handbuch der Praktischen Medizin," 2 Aufl. 4. Bd.

So far as the term diseases of *cell* metabolism is concerned, the use of that word is meant to convey no more and no less than that the origin of such disease is connected with a deficiency in the elemental parts of the human organism; such deficiency is inherited, that is, received in the body of the mother and accordingly present at birth as a tendency in the greater number of cases, while much more rarely it may be acquired at a later period. This conception is closely connected with the teachings of cellular physiology and pathology, starting from the principle that there exists no living substance that is not arranged in cells, and no function of such living substance that does not originate in the elemental life phenomena of the cell. Pflüger had long ago put forth the principle that in response to external influences various decompositions of an important character take place in the living proteid molecule, that is inseparable from the conception of life, the means for such changes being furnished either by the oxygen contained within the molecule or constantly taken up by it from without. During these changes carbonic acid gas is constantly formed, and indeed not only by the direct oxidation of carbon and the simple splitting of the carbonic acid molecule from the living protoplasm, but also by dissociation; that is, by the internal rearrangement of atoms and the separation of the new atom groups from each other. I need not enter here into further explanation of this conception for much of Pflüger's teachings no longer corresponds to the present state of physiological knowledge. M. Verworn, in submitting this theory to a thorough and adequate revision, struck the very essence of it by substituting for the living proteid molecule another conception, that of a biogen, which word corresponds to an idea of an active function. The biogens are the real bearers of life, and upon their continuous destruction and reformation is founded the whole life process in all its immense variety, it being self-evident of course that this conception includes not only the physiological state of this life process, but also those deviations from normal which are termed morbid by us. Accordingly, a physician has the right to seek the first cause of many general disturbances of the human organism in a primary anomaly of the biogens. The experience of daily life, indeed, has made this familiar to us, for we see that every individual possesses his own inherited peculiarity, often strikingly limited to his family, which in the last analysis must certainly have its seat in the elemental parts of his organism; that is, in the biogens. This fact may be observed in the pathological as well as in the normal state of the organism. Even à priori it is not to be doubted that the inherited and transmissible anomalies of the biogens can earlier or later make themselves evident in the form of various disease processes; it will be my task to show that their elementary disturbances consist in the incomplete formation or destruction of certain constituent parts of the human organism, which are then either retained in the body or more frequently perhaps are excreted in the urine. Hofmeister had extended the theory first proposed by Hoppe-Seyler that in all these disturbances a fundamental rôle is played not alone by incomplete combustion processes, but also by abnormal fermentations which are not exclusively destructive in their character; at the present day many good workers are occupied in the further development of these problems, and I would name among their labors the pioneer researches of my former fellow worker in the Göttingen medical clinic, Dr. V. Schittenhelm. The task then that is to be accomplished in the following pages is to show in how far my contention is correct, if at all, that obesity, gout, and diabetes mellitus are to be traced essentially to a certain deficiency of cell activity, at the same time more exactly defining the latter conception. In this connection it will become self-evident that the three diseases named above do not exhaust the list of affections in which the normal destruction of the intermediate products of metabolism is not finally carried out, but is halted as soon as a form that may be excreted by the urine is reached.

Let us then begin our task by considering the pathogenesis of corpulence and of the more advanced state of it, obesity, which is the most frequent of the three diseases that interest us. The primary symptom of this disease, the very root of all evil, is the abnormal increase of body fat, carried to a lower or higher degree of corpulence. This may originate in three different ways: in the first place, because of an increased amount of nourishment taken; in the second, because of diminished fat metabolism; and finally, because of both these conditions; the latter combination being made use of in the commercial fattening of animals. The fact that food is poor in fat, moreover, is no impediment to the appearance of the highest degree of corpulence, for nowadays almost everybody grants that the various classes of food material may under certain circumstances provide the elements for the formation of fat in the body. It may then be accepted as probable, at least, that the human body would become rich in fat under the conditions present in the fattening of animals, although it must not be forgotten that in so far as very extensive deposits of fat is concerned individual peculiarities are much more frequent in the case of man. One must come to the latter conclusion, because experience shows many men that eat almost everything and any quantity they please, leading withal no especially active life, without at the same time falling a prey to corpulence. We may therefore conclude that in the case of individuals not predisposed to corpulence there must be present certain characteristics preventing the deposition of excessive fat in the body, while in individuals predisposed to obesity, yet situated in otherwise similar circumstances, no such inhibitive action takes place, the degree of their obesity being apparently proportional to the number and kind of opportunities favoring such condition. The deposition of fat, so far as I know, occurs only in the protoplasm, the nucleus certainly remaining always free of fat. In the case of food poor in fat we must explain the deposition of fat in the protoplasm by supposing that proteids and carbohydrates may be transformed into fat by transposition of their elements or by some synthetic processes; this may occur more or less in a given patient, but always to a greater degree than under normal circumstances. Even if we were completely agreed about the manner of fat exchange in the animal body under normal conditions, we yet could not, as is often done, transfer such views to individuals who are predisposed to obesity; in their case the process of nutrition is doubtless accomplished in a different manner, a greater or lesser part of the food taken not being properly utilized in each given case. It is hard to state the real cause of this condition of affairs and, anyhow, such questions cannot be positively answered at the present time. Even had the study of the respiratory gas exchange in corpulent persons given us more uniform data than has been the case, we could still draw no gen-

eral conclusions from them in reference to the diminution of oxidation power in the individuals examined; it is to be remembered that the extent of the respiratory gas exchange depends upon numerous factors, such as the food and the formation of acid in the body, and therefore it in itself cannot solve the problem occupying our attention, namely, whether the consumption of fat is diminished in corpulent persons. Yet it is quite instructive to see from such researches that corpulent people show a much less perceptible rise of gas exchange, lasting, too, for a shorter period of time, after meals than is the case with thin individuals. Among the many hypotheses, most of which do not at all further our knowledge of this matter, the views of a former fellow worker of mine in the Göttingen medical clinic, Prof. Dr. R. Waldvogel, deserve close attention. He showed that 5 grams of sodium oxybutyrate aseptically injected into fat and into thin individuals are completely consumed in the case of the latter, with an accompanying increase of temperature, while no such rise is observed in corpulent individuals; the latter, therefore, are unable to consume fatty acids that appear in their intermediate metabolic processes in the same degree as is the case with non-corpulent persons. Even though Waldvogel himself raises an objection to his work in asking whether the mere excess of fat in the cells of corpulent individuals may not harm their fat-splitting ferments, yet in my opinion his experiment, in spite of the possible truth of this objection, may even now contribute to the explanation of the pathogenesis of corpulence, for the constant increase of fat in the cells of corpulent persons may be regarded as furnishing a condition quite favorable to a progressive development of obesity. That the deposit of fat in the cells cannot be looked upon as the most important element in the retarded oxidation of the sodium salt of β-oxybutyric acid injected into the body is seen from the results obtained by Waldvogel, a like retarded consumption of these fatty acids being noted in the non-obese diabetics, in whom certainly no increase of fat in the cells is to be presupposed. In any case we are justified in considering the results obtained by Waldvogel as furthering very much our understanding of the abnormal metabolism of fat in obese persons.

We turn now to the pathogenesis of gout, which is doubtless related to obesity in so far at least that the great majority of individuals suffering in their youth from gout, in their later years become more or less corpulent. The one fact at least has been established that gout depends upon a disturbance in an intermediate stage of metabolism, namely that of the nucleins. These are known to be the essential elements of the cell nuclei, and from their decomposition originate uric acid, xanthin, hypoxanthin, adenin, etc. The famous synthesis of the purin bodies accomplished by Emil Fischer gave rise at the same time to important advances in our knowledge of the nature of gout. He found that the compounds, since called nuclein bodies, contain a common radicle named by him purin; and by means of repeated analysis and synthesis he showed then that there are many intermediate forms between the individual members of the purin group, and finally succeeded in producing all the purin bodies contained in the urine. It is true that at present we cannot with absolute assurance trace gout to an abnormally abundant formation or diminished destruction of uric acid in the tissues. Some of the uric acid is formed in the organism originating in part at least from the nucleins of the destroyed cell nuclei, this making up the so-called endogenous uric acid, which is estimated to reach in quantity from 0.3 to 0.6 grams in a normal adult. The other, exogenous, portion of uric acid is brought to the body with the food in the form of highly complex compounds that are broken up into their elements in the intestinal canal and are absorbed in some form that has not as yet been clearly established. The quantity of the exogenous uric acid fluctuates within wide limits according to the purin content of the food. The solid organs may be considered to be the site of the changes undergone by the purins liberated in the course of metabolism, blood being probably merely a means of transportation of the purins and especially of uric acid. If the liver or the muscles prove inadequate for the destruction of uric acid, its quantity in the circulating blood may become increased, but no increased excretion of uric acid in the urine must necessarily follow, for the kidney is likewise capable of destroying the acid, assuming this function vicariously, when the other organs refuse to functionate. In any case, therefore, we are in no position to estimate even by the best methods of examination the quantity of uric acid formed or destroyed in the human body. It would be very improper, moreover, to form any opinion of the purin metabolism of gouty patients from that of healthy persons, although that is so often done. In recent times proper methods of research have cleared the matter in this direction and have improved our understanding of the phenomena. From this research work one is justified in concluding that in the case of gout deep-seated disturbance takes place in the endogenous changes of uric acid, this really self-evident proposition being one of the starting points for my views published in my works on gout almost a generation ago. For many reasons I assumed that uric acid is produced in an abnormal proportion in the muscles and in the bone marrow of gouty patients; this assumption, which was but an hypothesis in that stage of physiological and pathological chemistry, is now an accepted fact, at least so far as muscle is concerned. We know nowadays that muscle and probably also the red marrow of children, together with other tissues and organs, are able to transform purin bases into uric acid. But the most important starting point for my teachings on the pathogenesis of gout is found in my researches into those properties of uric acid that prove injurious to the tissues, different organs and tissues behaving differently in this respect. My original experimental and histological studies have shown that uric acid, being a powerful poison, injures the tissues by producing in them inflammation, necrosis, and death. Only when the tissue is dead, or is on the point of dying, there occurs the deposit of crystalline urates, just as in the analogous case of calcification. Sodium urate is the salt deposited, the same compound, that is, in the form of which uric acid circulates in the blood and other body fluids. The opinion of A. B. Garrod, who has done so much for our understanding of this affection, that gout may be diagnosed only in cases where such urate deposits are shown, is accordingly proved to be inadequate; the same is true of the other hypotheses founded upon the teachings of this investigator, that the kidneys, namely, are seriously affected even in the mildest cases and in the earliest stages of gout, and that an attack of gout may be caused by a sudden interruption of the function of the kidneys that has to do with the excretion of uric acid. In my opinion, this may be true only of those rare cases which I have called primary gout of the kidneys. To such cases may be referred the second portion of the statement made by W. H. Dickinson: "The rich

man enjoys a long life in spite of the gout that has attacked his limbs; the workingman is slain by a similar affection of the kidneys before his limbs are affected." Dickinson, however, has given no reasons in support of this opinion, which corresponds so well with daily experience. The development of the primary gout of the kidneys may perhaps be explained by the fact that a general stasis of uric acid, a "uricemia," caused by the retention of the acid, is developed in such cases upon the basis of a chronic nephritis, especially the interstitial form that is oftenest met in this connection. At the same time more of the other waste products of metabolism are retained with the progress of the disease, and such patients often die because of uricemia and uremia and their consequences, due to the lesion of the kidneys, long before there appear the typical symptoms of gout in the joints and extremities. Such nephritis, causing a primary gout of the kidneys, may itself develop secondarily upon a basis of existing gout, or it may have an altogether different reason for its appearance, such as chronic lead poisoning, for example, general gout, or primary gout of the kidneys developing in predisposed individuals parallel with the "lead-kidney" of such cases. (See Th. Oliver: Lead poisoning, etc. Edinburgh and London, 1894, p. 102.)

An especially important form of gout is the one named by me primary gout of the joints; it may however be more fittingly called primary gout of the extremities, as it usually spreads beyond the joints and attacks the surrounding skin and other parts just like erysipelas. In addition to the extremities in the accepted meaning of the word (arms and legs), the projecting portions of the head, such as the nose and especially the auricles, are often affected by this form of gout. To explain the origin of primary gout of the extremities I fall back upon the disturbance of purin metabolism in the large muscles as well as in the bone marrow, which has been already discussed. If in consequence of some accidental cause, such as trauma, the continuous stream of the fluids rich in uric acid content is retarded, especially in places favorable to stasis and congestion because of many obstacles offered to the return flow, such as the lower extremities, the great toes, and other parts of the foot, there may develop quite suddenly a typical attack of gout, followed often, though perhaps not always, by the deposition of crystalline urates, especially in the cartilages of the attacked joints. In my book on gout I have told the story of a famous colleague, a true martyr of gout, in whose joints at autopsy C. Weigert failed to find any abnormalities, although he had suffered from repeated attacks of gout, especially localized in these joints. If the statements of the few remaining authors who still believe that the deposit of urates is the primary phenomenon upon which only secondarily follows the disease of the tissues, were correct, then the absence of such deposits after many attacks of gout would be simply unthinkable, for a deposit of crystalline urates should certainly be expected in such case in every part of the body affected by the local process. Without going much further into this question, which I have repeatedly considered elsewhere, and which is of little relation to the problem occupying us at present, let me only state here the possibility and even indeed the probability, supported by the beautiful researches of T. van Loghem and Frenker, that gouty tophi could easily originate by the bursting of the fluid and lymph spaces of the connective tissue, thus allowing the escape of the juices rich in urates. These cause at first necrosis of the tissue upon which follows the crystallization of their urate content, the saying—*"corpora non agunt nisi soluta"*—being quite appropriate to this case.

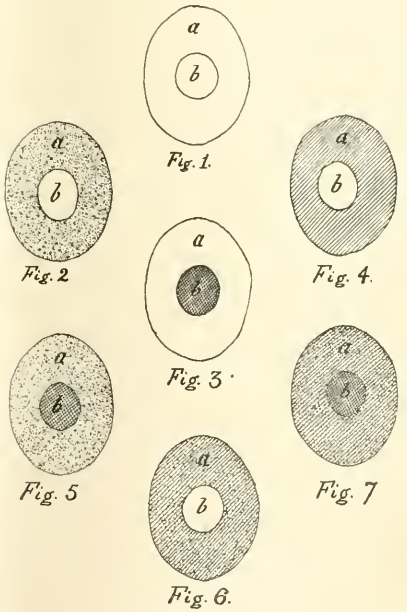
It seems shown herewith that the cause of gout is to be sought for in a disturbance of the intermediary stage of metabolism, especially that of the nucleins, growing probably out of an inherited tendency. Our conception of the hereditary disturbance of cell metabolism, moreover, finds still more support when we consider cystinuria and alkaptonuria. These anomalies, only lately brought to light, are doubtless connected with disturbances of proteid metabolism. The first of these, cystinuria, may be explained, as is seen from the experiments of Abderhalden, by the fact that not all of the cystin, formed in the intermediate stages of metabolism and not further oxidized, is excreted with the urine, thus causing the deposit of cystin in the tissues of the patient, in a manner quite analogous to the deposits of urates in gout. Cystinuria is well known to be an inherited affection, and this is probably true likewise of the second anomaly of proteid metabolism, alkaptonuria. In this affection tyrosin and phenylalanin reach only the stage of hemogentesic and uroleucic acids and appear in the urine in this form.

Passing now to a consideration of diabetes as an inherited disease of cell-metabolism, we see here an anomaly of carbohydrate metabolism, dextrin and small amounts of other sugars appearing in the urine, accompanied in the more severe cases by acetone, acetic acid, and B-oxybutyric acid, which are completely destroyed in a healthy organism. We might mention here that lately attention has been drawn to another anomaly of carbohydrate metabolism, namely to pentosuria, which is also occasionally an inherited affection. Here pentoses, that are certainly derived from endogenous metabolism, are excreted in the urine, not being used up in the body of the patient. Let us now return to diabetes, the cardinal symptom of which is glycosuria, appearing upon a diet which causes no excretion of sugar in other individuals. No constant quantity of carbohydrates can be named that may be taken without exciting glycosuria. When sugar appears in the urine only after a certain excess of carbohydrates has been taken and especially with the use of certain varieties of them, and not under other circumstances, we have to deal with a case of alimentary glycosuria. Such a condition could be called physiological if it were common to all men in like circumstances, but, as this is not the case, we are obliged to look upon it as essentially pathological. The ability of different individuals placed in like circumstances, to use up the carbohydrates of the food fluctuates within rather wide limits. When a diminished tolerance of the organism for the carbohydrates becomes chronic, and the excretion of sugar permanent, even with moderate intake of carbohydrate food, there results the condition which we term diabetes mellitus. The affection is the milder the more the carbohydrates ingested can be destroyed by the patient. The diabetics that are completely intolerant to carbohydrates, those, that is, that excrete sugar even when all carbohydrate food is excluded, manufacture it from a part of the carbohydrate-free material of the food or from the glycogen stored up in the biogens. This latter is probably obtained in such a case elsewhere than from carbohydrates, there being no carbohydrate material in the intake. Under the same conditions as a healthy man, that is, with the same intake of carbohydrates in the food, and, as I have shown, with the same body weight, the diabetic excretes less carbonic acid gas and takes in a correspondingly smaller amount of oxygen. I have already pointed

out in reference to the respiratory gas exchange of fat individuals, that this coefficient is affected by many factors, such as food and the amount of acid formation in the organism. The data that lead us to assume a diminished oxidation power in diabetics may therefore be used only if these factors are excluded. On the other hand, Waldvogel and later Leo Schwartz have shown by the use of injections of sodium B-oxybutyrate that the oxidation capacity in diabetics is diminished, this being due to insufficient internal respiration. I imagine that the carbonic acid, decreased in amount, may in its nascent state give an impetus to the excretion of sugar, for laboratory experiments teach us that the activity of the diastatic enzymes may be retarded not only by neutral but to a certain degree also by alkaline solutions. It seems to me that in this situation an hypothesis falling back upon the biogens of the diabetics is allowable, in order that this condition may be cleared up. The property of carbonic acid gas to retard the action of the diastatic enzymes mentioned above, leads one to the idea that this gas may, in its nascent state, be the regulator of the formation of sugar from the glycogen stored up in the biogens. Within the biogens there are found side by side glycogen (which in diabetes may be formed too abundantly, being certainly found in unusual places in this condition, *e.g.* in the brain) and the diastatic ferment which may also be present in an abnormal quantity. However that may be, there is justification for the hypothesis that when the action of the diastatic enzymes is insufficiently regulated, because there is lack of carbonic acid in the presence of the diminished internal respiration, the almost indiffusible glycogen is more rapidly transformed into the extremely diffusible sugar, which thereupon appears immediately in the body fluids and then in the urine. Accordingly, I think that the glycosuria in diabetes is due to the fact that the sugar present or formed during the intermediate steps of metabolism is more or less completely excreted before it can be assimilated in the interests of the whole organism. With the help of the diminished production of carbonic acid gas in the internal respiration, caused by a defect of the biogens, we are able to explain to ourselves the increased destruction of the body proteids which appears sooner or later in the course of diabetes. The carbonic acid gas is able to change certain proteid bodies into a stable condition by precipitating them from their solutions, this being especially true of the globulins, that are present most abundantly in the liver and in the muscles. When oxygen is admitted, dissolving the precipitated proteid bodies, they again slowly or quickly assume a labile condition.

Glycosuria, as well as well marked diabetes mellitus, depend in the last analysis upon a defect of the biogens, that is, of the protoplasm, which, however, at the present time cannot be more exactly defined by either microscopical or chemical examination. We know this defect however from the effects it produces, *i.e.* from the influence exercised by the diminished capacity for oxidation. Experience teaches that the latter may not only be transmitted by inheritance, but often may coincide with neuropathic tendencies peculiar to some families The greater is this deficiency of the protoplasm the earlier and the stronger is its disturbing action in otherwise similar circumstances; at the same time, even a less strongly expressed diabetic tendency may become of import when accidental causes, the so-called predisposing moments, give impetus to its action, contributing in their own way to the damage of the protoplasm. I would mention here the injurious effects of the diseases of the nervous system of trauma accompanied especially by concussion of the body, the various infections, diseases of the liver, and especially those of the pancreas, the latter being of peculiar import in this connection. The rôle of the pancreas in the origin of diabetes mellitus I imagine to be as follows: Because of the failure of its function as a detoxicating organ the cells of the body are injured in such a fashion that they become less active in function, and only serve the ends of internal respiration in a defective manner. The individuals thus affected then fall a prey to all the consequences of this condition. In my opinion, diabetes mellitus is not a symptom of the disease of the various organs, but is a disease *sui generis,* the first cause of which lies in a deficient character of the protoplasm, that is transmissible by inheritance. In consequence of this defect there arises the anomaly of the carbohydrate metabolism present in this disease. If we may thus call obesity, gout, and diabetes mellitus diseases of cell metabolism, dependent primarily upon a defect of the cells, then it becomes at once clear that each one of them may be traced to changes in the biogens different in localization and in character.

That these three diseases are, nevertheless, closely related to each other is no less plain, two of them and sometimes all three often affecting one individual simultaneously. We are far removed at present from being able to imagine satisfactorily the intimate relations between these three diseases seen in this connection. The seven figures below represent schemata of cells, and are meant to give a certain picture of the relations between the conditions here considered. In these figures *a* repre-



sents the protoplasm, while *b* stands for the nucleus Fig. 1 represents schematically a normal cell, Fig. 2 a cell in obesity (protoplasm dotted), Fig. 3 a cell in gout (cross-hatched nucleus), Fig. 4 a cell in diabetes mellitus (single-hatched protoplasm). Figures 5, 6, and 7 represent respectively

the combinations of obesity with gout, of obesity with diabetes mellitus, and of all three of these diseases of cell metabolism transmissible by inheritance.

IS THERE A SURGICAL TREATMENT FOR CONSTIPATION?

By CHARLES B. KELSEY, M.D.,

NEW YORK.

The effort to establish a legitimate operative treatment for chronic constipation has not as yet inspired much confidence in the profession at large, and for very good reasons. It has gone through various stages, each of which has had its advocate and short-lived popularity. As each has failed lamentably to do any good, and consequently to be recognized and adopted by the truth-seeking majority of the profession, no matter how enthusiastic and honorable its sponsors may have been; the motto of these has ever been onward and upward from the sphincter to the "valves," and from these to the sigmoid and colon, until a regular chain of operations has been established which separately or combined have been and are still advocated as liable to produce the desired effect.

The first link in this chain is stretching the sphincters, and a few years ago a very large percentage of my own patients came to me with the preliminary statement that their sphincters had already been stretched, but without any benefit. The stretching was sometimes forcible and thoroughly done under some form of general anesthesia; at others only partially done with the finger and without anesthesia, but beyond the damage to the patient's finances attendant upon a surgical operation, neither good nor harm resulted. The number of these patients has steadily decreased, however, and perhaps the fad is becoming a trifle worn.

And yet fads in surgery usually have some foundation in fact as this may have had. There is a rare spasmodic contraction of the sphincters, usually but not invariably attendant upon fissure, which will prevent defecation and can only be overcome by stretching or incision. The condition without the presence of a fissure to induce it is exceedingly rare, so rare as to be a curiosity. The muscle under nervous excitation becomes hard, firm, absolutely unyielding, and any attempt to pass it either from above or below is exquisitely painful. As a result the rectum may become distended with impacted feces and surgical interference be the only cure. This, however, is not constipation in any proper sense of the word. Nature is only anxious to accomplish its function of defecation, and it is this which causes the suffering; but by no effort of the will can the sufferer relax the obstacle.

Whether the practice of stretching as a routine treatment had its origin in this well recognized but very rare condition, or in entire ignorance of it, it is impossible to say. It is much more probable that it grew out of the legitimate cure of fissure by stretching and was gradually extended till practised in any and all cases where the patient complained of trouble with the rectum from constipation or almost any other condition.

The next step upward in chronological order was to cut the "valves of the rectum."

It is a curious thing that what Van Buren said of these so-called valves and of the so-called "third sphincter" so many years ago, that they had "neither certainty of location nor certainty of function," has not yet, in spite of all the work of all the proctologists, been proved to be an error—for the simple reason that it is as true to-day as it was nearly half a century ago, when he carefully studied the subject. From this point is is rather a far cry to assert that they are the cause of constipation and to base a surgical treatment for that condition upon their division.

I will try to state in few words exactly what we actually do know about these anatomical points. The walls of the sigmoid and the rectum are much heavier than that of the small intestine, and this is due in great part to an increase in the amount of muscular tissue, both longitudinal and circular. As the longitudinal fibers become more marked and are gathered into distinct bands which have a good deal of uniformity, so, but with much less uniformity, do the circular. As a result there is liable to be found by close dissection certain points in the lower sigmoid and rectum where the circular fibers are so increased as to be distinctly demonstrable to the naked eye. This constitutes the basis for the idea of a third sphincter.

Have these circular bands any constant location? On the contrary, they are found anywhere along the entire length of the rectum and lower sigmoid. Is there one even generally located so as to constitute an anatomical boundary between the end of the sigmoid and the commencement of the rectum, which could even by a stretch of imagination be considered an obstruction to the passage of feces from one to the other? No anatomist has ever described any such thing, and no anatomical preparations have ever been shown to demonstrate it. Have these bands any sphincteric action? Not the slightest.

What, then, is the scientific basis for a routine treatment of constipation which consists in introducing dilators of any form far up into the rectum "to stretch the constriction between the sigmoid and the rectum so that the feces may pass?"

So much for the third sphincter, which is in no way to be confounded with the "valves" of the rectum, though they have frequently been described as one and the same thing.

The mucous membrane of the rectum is too large to cover smoothly and evenly the muscular wall which it lines. It is hence of necessity gathered into folds or rugæ. These are the "valves." Are they constant in location? On the contrary, there may be one, two, or three of them, and they may occupy any positions in the rectal pouch. Have they any valvular action? None. Are they sufficiently firm in structure to constitute an obstacle to the passage of a solid fecal mass? No. Have they any known function? None has ever been assigned to them. We are speaking now of the normal anatomy of the parts. But just as there is a rare spasmodic affection of the sphincters which may prevent defecation, so, though even more rarely, there has been found a congenitally hypertrophied condition of one of these folds of mucosa, with increase of fibrous tissue constituting a partial stricture causing some obstruction. That the fad for dividing these folds as a routine treatment for constipation originated in or has any connection with this pathological fact we very much doubt. When such a condition exists we have to deal with a congenital stricture—one of the rarest diseases in surgery.

Many ingenious instruments have been invented for cutting or destroying these normal folds of mucous membrane. Some cut with a concealed bistoury, others clamp the fold until it sloughs away. The list of dangerous hemorrhages caused by their use is not a short one.

It is, perhaps, not flattering that although this cure for constipation has been written up for a

decade in American literature and is still practised, though less frequently than at first, no English or continental writer on diseases of the rectum, so far as my reading goes, has ever considered it scientifically worthy even of mention.

The next step onward in chronological order came with the introduction of vibratory massage into general practice, and this is still in vogue. It consists in the introduction of a hard rubber plug about three inches long into the anus, attaching an electric motor to this, and starting it vibrating. For those who have no suitable electrical apparatus the index finger is often substituted. Never having practised this method of excitation of the activity of the nerves and vessels of the part, I can give no details as to whether it is commonly employed daily or at longer intervals. It is a subject difficult to write of with moderation, and it is best to pass it lest offence be given.

By no means disheartened by lack of success, the next step was to abandon all that had gone before and even the rectum itself and strike boldly at the sigmoid through an abdominal incision. Surely if stretching and vibrating the anus, cutting the folds, and stretching the hypothetical narrow parts, had failed, the cause of all evil must be in the curved shape of the sigmoid; therefore it must be straightened out and raised up and anchored to the abdominal wall to keep it straight, that nature may be improved upon and feces allowed to pass.

This operation was, so far as I know, first devised and practised by myself years ago as a cure for bad cases of prolapsus. It came from seeing my gynecological friends practise ventral fixation of the uterus, and was attended, as it still is, with a certain amount of success. There is a certain mechanical difficulty, however, about applying it in the treatment of constipation, due to the fact that though the curve may be changed and rendered more acute and less movable by anchoring any part of it, it cannot be removed without actual resection.

There is, moreover, danger of fatality in this operation, for adhesions formed in this way have been found to cause internal hernia and strangulation through apertures made by the bands. No rules seem to govern those who operate for constipation as to how the normal position of the gut should be modified, it being quite sufficient to find some free portion and suture it. This curve is generally shaped like the Greek letter omega rather than sigmoid. It is evident that by fastening the most movable part of the loop up from the pelvis to the abdomen we make the curves much more acute and reduce their mobility. If any effect is produced it would seem to be to substitute a sharp, fixed, angular flexure, for a gentle sweeping curve, and this does not appeal to the average mind as liable to facilitate the passage of feces.

All these surgical operations are based on one idea and it is quite in order to ask on what besides the merest baseless assumption does this idea that constipation is due to mechanical obstruction rest? Who has taught it, who ever asserted it, or attempted to prove it? The anatomy of the large intestine is about the same in all of us; why are not all men constipated if that normal anatomy is so faulty? Moreover, where are we to stop in our efforts to make the large intestine a straight tube, and remove its irregularities, or are we to stop at the large bowel at all? After doing away with the sigmoid flexure there will remain still the splenic and hepatic, and the almost right-angled arrangement at the head of the colon, the sharpest and most fixed of all, should certainly be straightened out.

Finally, the profession certainly have a right to study the results of this kind of surgery as to benefit or cure. What are they? The writer has heard some very bitter complaints from those who have submitted to it of the mental anxiety and suffering attendant upon a useless surgical operation, loss of time, and waste of money, and in the cases he has observed there has certainly been no improvement. Is this the usual result, and are these complaints justified?

44 East Twenty-ninth Street.

THE THERAPEUTIC VALUE OF APOMORPHINÆ HYDROCHLORIDUM.

By EUGENE L. FISK, M.D.,

NEW YORK.

Apomorphine may properly be termed a therapeutic "freak." Separated from morphine merely by a molecule of water, *i.e.* morphine, $C_{17}H_{19}NO_3 - H_2O = C_{17}H_{17}NO_2$, apomorphine—it gives little evidence of its close chemical relationship to a powerful narcotic alkaloid when administered by the mouth, even in relatively large doses, and acts as a harmless, though most efficient, expectorant. Administered subcutaneously, however, it is a powerful remedy, and when moderate doses are exceeded, even a dangerous one.

This interesting drug was nearly discovered some sixty years ago by one Arpe, who heated morphine in a tube with sulphuric acid, and possibly secured an impure sulphate of apomorphine, which was afterwards termed "sulpho morphide" by Laurent and Gerhardt. Apparently it remained little more than a chemical curiosity until 1869, when Augustus Matthiesson and C. R. A. Wright read a paper before the Royal Society "On the Action of Hydrochloric Acid on Morphine"[1] These investigators had succeeded in forming the artificial alkaloid, apomorphine, through the dehydration of morphine by a process essentially the same as that now employed. Morphine is inclosed in sealed tubes with excess of hydrochloric acid and heated for several hours to 140° to 150° C. After cooling, the contents of the tube are diluted with air-free distilled water, saturated with sodium bicarbonate, filtered, and apomorphine is extracted with chloroform or ether. The hydrochloride is formed by adding a small quantity of hydrochloric acid.

It was also found that the alkaloid could be formed from codeine by a similar process. The chemical relations may be expressed as follows:

Morphine, $C_{17}H_{19}NO_3 - H_2O = C_{17}H_{17}NO_2$, apomorphine.

Codeine, $C_{17}H_{17}(CH_3)HNO_3$ yields first $C_{17}H_{20}CLNO_2$, and then splits off methyl chloride, CH_3CL, and leaves $C_{17}H_{17}NO_2$, apomorphine.

Apomorphinæ hydrochloridum, the salt used in medicine, is composed of white or grayish crystals turning green on exposure to light, and soluble in 39.5 of water and 38.2 of alcohol.

Gee[2] was one of the first to test the drug physiologically, and noted its emetic properties. Although testimony regarding the effect of apomorphine on the nervous, circulatory, and muscular systems is somewhat conflicting, the results of exhaustive experiments independently conducted by Harnack[3] and Reichert,[4] offer a reasonably safe guide to the action of the drug.

In poisonous doses apomorphine first excites the cerebral centers, producing delirium, followed by depression and paralysis of the respiratory centers. The accelerator fibers in the vagus are stimulated, causing increased rapidity of the pulse. There is

an initial period of lowered blood pressure, due to direct action on the heart muscle; an intermediate period of increased pressure (stimulation of the vasomotor center, temporarily offsetting the effect on the heart), and finally a period of lowered pressure due to the action on the heart muscle.

The excised heart of the frog is paralyzed by apomorphine, and there is evidence that in mammals it acts as a direct poison on both striped and cardiac muscle. Respiration is first stimulated and then weakened.

Careful experiments have shown that its emetic action is centric, probably due to stimulation of the vomiting center, which Thumas claims to exist in the medulla in the immediate vicinity of the calamus scriptorius.

Rossbach claims that the bronchial secretion is increased by direct action on the mucous glands of the respiratory tract and stimulation of the glandular nerves.

Reichert,[5] in experimenting on animals, noted that although the motor and sensory nerves were both decidedly depressed, without evidence of stimulation, a condition of hyperesthesia subsequently suddenly developed, accompanied by violent tetanic convulsions, shown by experiments to be of spinal origin. To explain these contradictory manifestations he postulated the existence of certain spinal reflex inhibitory centers analogous to those discovered by Sectshenow at the base of the brain, upon which apomorphine acts as a depressant.

So much for the laboratory reactions and manifestations of this interesting drug. Although nearly forty years have elapsed since apomorphine was presented to the profession, and many eminent British and Continental authorities—notably Ringer,[6] Murrell,[7] Rossbach,[8] Whitla,[9] Binz,[10] Weill,[11] and Gee—have correctly described its dosage and clinical effects and highly indorsed its use as an expectorant and even as an antispasmodic and hypnotic, the drug still remains more or less neglected, so far as its expectorant uses are concerned, and our leading authorities describe it chiefly as an emetic, to be administered subcutaneously. Many writers on respiratory affections ignore the drug entirely, or quote foreign authorities as to its value, showing no personal experience with its use, or such a limited experience with insufficient doses as to offer but a poor guide to its proper administration. It is needless to quote all such authorities; a few examples will suffice:

Gould's Medical Dictionary: Emetic dose—1-20 to 1-10 grain hypodermatically, or 1-10 to 1-6 by the mouth. "An expectorant in small doses."

Hare's Therapeutics: Emetic dose—1-10 to 1-5 grain, hypodermatically; expectorant dose—1-40 to 1-25 grain by the mouth.

W. E. Dixon, Manual of Pharmacology, 1906: Hypodermatic—1-20 to 1-10 grain; by the mouth—1-10 to 1-4 grain.

National Standard Dictionary: Emetic dose—1-10 to 1-5 grain, hypodermatically. Expectorant dose—1-40 to 1-25 grain by the mouth.

H. C. Wood's Therapeutics, 1906: Emetic dose by the mouth, double hypodermatic dose; expectorant—1-16 to 1-12 grain.

U. S. Pharmacopœia (8th Dec. Rev.): Expectorant—1-30 grain; emetic—1-10 grain.

British Pharmacopœia: Invariably produces vomiting in doses of 1-5 grain by the mouth and 1-10 grain hypodermatically. Also gives emetic doses by the mouth—1-12 to 1-4 grain.

J. P. Remington, Practice of Pharmacy, 1905: Expectorant—1-30 grain; emetic—1-10 grain. Often given hypodermatically.

Saunders Questions Compends—Essentials of Materia Medica—Morris, 1906: A powerful emetic, *however administered*. Emetic dose by mouth—1-10 to 1-8 grain.

Squibb's Materia Medica: Emetic—1-12 grain; expectorant—1-30 grain.

Merck's Manual: By the mouth, expectorant—1-60 to 1-20 grain; emetic—1-15 to 1-8 grain; hypodermatically—1-20 to 1-10 grain; hypnotic—1-40 to 1-30 grain.

The internal doses noted above appear to have been fixed, not from personal observation of its effects, but either from tradition or from a consideration of the mathematical relations that exist between the hypodermic and internal dose of other alkaloids.

Any physician who has had wide experience in prescribing apomorphine as an expectorant will at once note the insufficiency of the expectorant doses given by these authorities; and so far as the emetic dose by the mouth is concerned, the drug is practically useless as an emetic when administered in that fashion. Although it is very rarely used as an emetic by the mouth, nevertheless, the statement that 1-10 grain, or even 1-2 grain, so administered, could be relied upon as an emetic, is wide of the mark.

The possibility of depression, collapse, and untoward effects from the use of apomorphine is often referred to by standard authorities, but care is seldom taken to explain that such effects are not to be feared when the drug is administered by the mouth, even in relatively large doses.

Binz reports a case in which the hypodermic injection, near the ensiform cartilage, of 1-15 grain in a subject suffering from chronic bronchitis and emphysema caused death within seven minutes from collapse, without vomiting. There is a possibility that in this case amorphous hydrochloride of apomorphine was administered instead of the crystalline.

According to Boyer and Guinard[12] the amorphous form differs radically in its effects from the crystalline form, causing in full doses prostration and collapse. However, this case and others of a similar nature reported in the literature, in which alarming symptoms have followed the administration of the drug hypodermically, only emphasize the remarkable difference between the internal and hypodermic effects.

The rationale of this difference is difficult to determine. Murrell suggests the slowness of absorption as an explanation of the failure of internal doses to excite vomiting, but that seems like a restatement of the problem without answering it.

Reichert, in his experiments on animals, found that there was a critical point in the dosage of apomorphine where it ceased to stimulate the vomiting center, but depressed or paralyzed it. Likewise. Max Quehl,[13] Rossbach, and others have pointed out that large doses are narcotic and not emetic. This would explain the failure of large internal doses to produce vomiting, but does not account for the absence of other narcotic influence, nor does it explain the negative effect of small internal doses.

The fact that apomorphine is a decomposition product, and that its solutions are alleged to be very unstable, suggests the possibility of some change taking place within the stomach, especially as large internal doses in man seem to have practically no physiological effect, aside from the expectorant action, and are unaccompanied by the evidences of excitement or depression always observed when the drug is administered in full doses hypodermically. Reichert, however, in his experiments on dogs, noted that the drug acted with certainty as an

emetic when administered by the stomach, although somewhat more slowly; and the fact that Murrell administered it in full doses by inunction—also by means of a throat spray—with excellent expectorant results, and without evidence of the centric effects observed from hypodermic administration, would tend still further to obscure the problem.

Cushney[14] and others regard the expectorant effect as really the first stage of vomiting, and the drug is, therefore, classified among the depressing expectorants. It is doubtless true that all specific emetic substances also have an expectorant effect, and that it is impossible to excite the vomiting center without causing a flow of mucus in the respiratory tract[15]; also, that there is a close association between the vomiting and respiratory centers, the act of vomiting in adults being largely controlled by the muscles of respiration.

Rossbach, however, is alleged to have shown that apomorphine has a direct stimulating effect on the mucous glands and glandular nerves of the respiratory tract. Clinically, the fact that the decided expectorant effect of large internal doses may be obtained without accompanying depressant or other centric effects tends to support the view of Rossbach that the expectorant action is at least in part peripheral. For example: Babcock[16], one of the few American authors to show a first-hand knowledge of the internal effects of apomorphine, cites the case of a middle-aged patient suffering from bronchitis, who took 2½ grains four times a day without ill effect except once, when the remedy was taken before breakfast. Murrell mentions similar cases, and is fully quoted in this regard by Shoemaker. It is possible, however, that there is some slight sedative effect from the drug when administered in this manner, as the cessation of cough and quiet rest afforded in acute laryngeal and bronchial affections may not be due solely to the relief of local conditions.

On reviewing the evidence, therefore, it would appear that we are at present without an entirely satisfactory explanation of the vagaries of apomorphine. Whatever views may be held regarding the physiological modus operandi, the clinical fact remains that relatively enormous doses may be administered by the mouth without other important effect than a decided expectorant action.

During the past ten years I have prescribed the hydrochloride of apomorphine very extensively in respiratory affections, giving it the preference over all other expectorants in conditions where a remedy of this class, which excites a flow of mucus, is indicated. I have found it especially serviceable in cases of acute or subacute laryngitis, tracheitis, or bronchitis, where there is a dry, turgescent membrane or the bronchial tubes are obstructed with tenacious mucus. The violent cough in these cases is often most distressing, causing cerebral congestion and disturbance of rest. The relief afforded by apomorphine, administered in doses of 1-8 to 1-4 grain every two or three hours, is quite remarkable when contrasted with the frequent failure of other remedies—topical or systemic—to relieve promptly such conditions. In no instance have I observed any nausea or depressing sequelæ from the administration of the drug in these doses, even when given to aged or debilitated patients. I recall in particular the case of a patient ninety years of age, with advanced cardiovascular changes, suffering from subacute bronchitis, who took 1-8-grain doses every two or three hours without other result than liquefaction of the sputum and abatement of cough. No depression was noted, and not the slightest evidence of nausea. On the other hand, I have frequently given it to young children in doses of 1-60 to 1-12 grain, the latter dose to a child of eight years. In these little patients no depressing effects were noted, but I fancied that the quiet rest often secured at night was due not entirely to the cessation of the cough, but partially to some sedative influence. In these cases, and all others where the drug was administered in full doses at frequent intervals, there was a total absence of any of the usual after-effects of narcotic remedies.

I have also used this remedy in bronchial asthma with excellent effect, and believe that here it may be combined, when necessary, with small doses of morphine or heroine. In a large class of cases where heroine is now so frequently prescribed, apomorphine would be found more serviceable, and free from the objections that obtain to heroine. The latter drug, if given in sufficient doses to control fully an obstinate cough, may cause severe headache, constipation, and other depressing effects, and there is also a possibility of the formation of a habit. With apomorphine there is not the slightest possibility of a patient becoming addicted to the drug, as it offers absolutely no temptation in that direction.

The fact that apomorphine may be given simultaneously with morphine, heroine, or codeine, without increasing the narcotic effect, further illustrates the therapeutic dissociation from these remedies, and greatly increases its value as an expectorant through the opportunity it affords of securing the quieting effect of opiates without at the same time checking secretion. Lauder Brunton recommends the combined administration of morphine and apomorphine in cases where "there is difficulty in breathing, continual cough, and thick, tenacious mucus."

Although various observers[17] have strongly urged the use of full internal doses of apomorphine as an expectorant, I am forced to the conclusion, from the testimony of numerous pharmacists and physicians, that there is little disposition on the part of the profession to utilize fully the valuable expectorant qualities of the drug, probably owing to its high reputation as an emetic and the fear that unpleasant results may follow its administration. I have had the same experience reported by Babcock, in regard to the hesitation often manifested by pharmacists in filling prescriptions for moderate doses. Patients have been warned that the drug would produce vomiting, and must be taken with caution. Of course, it is proper for the physician to give such warning as a routine matter, although in no instance has any untoward result been reported by my patients, notwithstanding the probability that the amorphous form, which is very much cheaper than the crystalline, is frequently dispensed. I have lately, however, taken the precaution to specify the crystalline form, lest an overdose should be taken by some individual with an idiosyncrasy against the drug.

As regards the other uses of apomorphine, it has been recommended by competent observers in a wide range of conditions where hypnotics, sedatives, or antispasmodics are indicated, including mania, trismus, hiccough, strychnine poisoning, and oil of tansy poisoning.

Laurencin,[18] Faucher,[19], Weill, and Gower[20] reported good results in epilepsy and chorea by hypodermic administration. Tull[21] reports the case of a child, æt. 15, suffering from chorea; treated with 1-40 grain hypodermically, followed by 1-20 grain, per os, every three hours. Quiet sleep and uneventful recovery ensued under the use of arsenic.

Douglas,[22] Tompkins,[23] Lewis,[24] Bechtet,[25] and others have highly endorsed apomorphine in the

treatment of acute and chronic alcoholism, and its employment for this purpose has become quite general. Lewis and Bechtet used it in delirium tremens with good effect; but others, notably Coleman and Polk,[26] believe it to be harmful in this condition owing to the possibility of profound depression resulting. The latter observers tested the drug in a series of three hundred cases of alcoholism, in the alcoholic wards of Bellevue Hospital. It was clearly demonstrated that hypodermic doses ranging from 1-30 to 1-5 grain acted as a decided hypnotic in 67 per cent. of cases, but its effects were usually limited to a few hours, and it acted best when followed by some other hypnotic, such as bromide, chloral, etc. Thirteen patients were given apomorphine by the mouth in doses of 1-10 to 1-4 grain. Vomiting occurred in none of these cases, and only two slept. The marked difference between the internal and hypodermic effects is very clearly shown in these tests.

It is possible that better results would have been obtained in the cases of delirium tremens treated by Coleman and Polk if strychnine had been simultaneously administered (1-30 grain each), as in Bechtet's cases.

Most standard text-books state that the drug should not be used in tablets or solution if it has undergone discoloration. A number of authorities, however, deny that this simple oxidation process in any way impairs its efficiency, especially if the tablet or solution was originally prepared from the pure crystalline salt. Murrell states that pure solutions remain unimpaired for one year, even though discolored. In emergencies I have often used solutions that were several months old, with the usual effects. The tendency to dispense the cheaper and more soluble amorphous form is evidenced by the following incident: Recently I prescribed apomorphine in a case of bronchitis, and specified the crystalline form. The pharmacist to whom the prescription was presented was unable to compound it until the following day, stating that he was all out of the crystalline form and was unable to procure it at any of the neighboring downtown pharmacies. On inquiring, I was frankly informed by the pharmacist that he always dispensed the amorphous form unless the crystalline was specified. The importance, therefore, of specifying the crystalline salt is quite evident.

Summary.—(1) The effect of apomorphinæ hydrochloridum, when administered by the mouth, is widely different from the hypodermic effect.

(2) Hypodermically, it is a most valuable centric emetic in doses of 1-20 to 1-6 grain, acting speedily, certainly, and gently, even in cases of narcotic poisoning prior to the stage of coma. Average adult dose, 1-10 grain. Also recommended to be tried in all cases where hypnotics or antispasmodics are indicated, in doses preferably somewhat less than the emetic dose, depending upon the tolerance of the individual, i.e. 1-40 grain or more.

(3) When given hypodermically to children or debilitated subjects the possibility of its depressing effects should be borne in mind, and appropriate doses of strychnine simultaneously administered.

(4) By the mouth, its centric effects are so uncertain as to render it useless as an emetic and of little value as a hypnotic. The effect is practically limited to expectorant action. Average adult dose, 1-8 grain every two or three hours, dissolved in syrup of wild cherry or syrup of lactucarium, with a few drops of dilute hydrochloric acid to insure solution.

(5) It does not increase the effect of other narcotics, such as morphine, codeine, or heroine, which may be simultaneously administered when it is desired to lower the excitability of the respiratory center without checking secretion. Strychnine may also be simultaneously administered in debilitated subjects for its stimulating effect on the respiratory center and to forestall possible depression, although even in the case of delicate children there is little fear of such depression from the administration of the pure crystalline preparation by the mouth.

(6) Apomorphine, like other expectorants of its class, if used at an improper stage, when there is abundant secretion, or pushed to the extreme, may flood the bronchial tubes with mucus and drown the patient in his own secretion, especially if he lacks muscular power to expectorate. Such results, however, are not to be feared from an intelligent use of the remedy.

(7) Crystalline apomorphinæ hydrochloridum should always be specified. There is a slight danger of adulteration with morphine if the drug is not thoroughly washed when manufactured. On general principles, the fresh preparation should be used if possible, but a greenish discoloration of tablets or solutions does not necessarily contraindicate their use, especially if originally prepared from the pure crystalline salt by a reliable drug firm.

Cold Tea in Typhoid Fever.—While carrying out a series of experiments to ascertain whether the *Micrococcus melitensis*, the germ of Malta fever, would survive in milk when added to tea, Major J. G. McNaught of the Royal Army Medical Corps recently made an investigation into the action of cold tea upon the *Bacillus typhosus*. The results of his experiments showed that in five hours the *Micrococcus melitensis* was completely destroyed, and in the case of the *Bacillus typhosus* contact with the cold tea for four hours greatly diminished the number of the bacilli, and at the expiration of twenty hours none could be recovered from the tea. He considers the experiment of great interest with reference to the question of the use of cold tea as a substitute for water in the soldiers' canteen, as a safeguard against typhoid infection.

THE CLINICAL SIGNIFICANCE OF THE SYMPTOM, HEADACHE.

By E. CASTELLI, M.D.

NEW YORK.

Owing to the fact that the pathogenesis of headache finds its most rational explanation in the stimulation of the anatomical nervous elements of the dura mater, I think it advisable to give first a brief anatomical sketch of the innervation of the dura mater, and proceed then to the discussion of the argument.

The dura mater is provided with a very fine and rich net of nervous elements, consisting of nervi propri, nervi vasomotores, and Krause's sensory corpuscles.

The nervi proprii anastomizing with each other form a rich reticulum whose fibrillæ end freely among the endothelial elements of the laminæ parietalis arachnoidis. The Krause corpuscles are delicate terminal sensory elements that, when pressed against the rigid thecæ osseæ of the cranium, on account of changes taking place in the intracranial pressure, cause severe violent pains. The irritating stimuli are received by the nervous reticulum, and from it transported to the sensory centers through the branches of the fifth nerve.

In the anterior portion of the dura mater takes place the distribution of the filum ethmoidalis of the ramus nasalis of the ophthalmic branch of Willis.

In the middle portion of the dura mater takes place the distribution of the ramus meningeus, derived from the third branch of the fifth nerve, which follows the arteria meningea media.

To the posterior portion of the dura mater, and especially to the tentorium, goes the so-called nervus recurrens arnoldi, a branch originating from the ophthalmic branch of Willis, before its entrance in the foramen orbitale.

Characters.—Headache constitutes one of the main symptoms in the syndrome of almost all nervous affections, and one of the auxiliary symptoms of many other affections of the organism. In presence of the symptom, headache, we must first of all establish its characters; we must find out if the headache is a localized or a generally diffused one; if it is constant, intermittent, or remittent, if it is regularly or irregularly intermittent, but we must especially endeavor to establish the connection existing between the appearance of the headache and the different circumstantial evidences of physiological, pathological, or psychological disturbances, preceding the appearance. The relation between cause and effect is the only reliable key to diagnosis, as the knowledge of the fact that there is no effect without a cause is the only scientific axiom leading to the conquest of truth in all lines of human activity. When the headache is localized in special regions of the cranium, we must bear in mind that the regions of election of localized headache are in order of frequency the following: (*a*) frontal, (*b*) temporal, (*c*) occipitalis and bregmatic, (*d*) parietal.

Sometimes the headache may be unilateral, being limited to one-half of the head, or it may be localized to a single point, as we notice in the so-called clavus hystericus, in which the pain is localized in the bregma. We may also have a localized headache in the syphilitic gumma of the meninges, or in tumors of the meninges, specially sarcoma, when determining lesions of the cranial bones in any one point. In these cases we notice an eccentric irradiation of the pain detectable on percussion, the pain being very severe at the point corresponding to the meningeal lesion, and diminishing gradually in intensity as percussion recedes from such point. The percussion of the skull as a systematic procedure of physical examination is not greatly used among physicians. Bechterew and MacEwen are credited with having called attention to the importance of such a procedure as a method of detecting intracranial lesions. Still I must acknowledge that so far, with the means at our disposal, percussion of the cranium can give but very little help in the diagnosis of the nature of intracranial lesions. It is only of value when used to detect the zones of superficial or deep-seated pain of the head. The type of pain and its topography will facilitate our efforts in determining whether the pain is purely functional or due to changes taking place in the anatomical substrata.

In all processes of periostitis, osteitis, localized meningitis, syphilitic gummata, etc., the lesion corresponds to the point of most exquisite painfulness of the skull detectable on percussion; while in all neuralgic forms, in migraine, in neurasthenic hyperalgiæ, and in diffuse meningitis, the sensation of pain produced on percussion has no value, because in these cases the percussion of any point whatever of the skull will produce pains irradiating to all parts of the skull or to one-half of it.

The subjective symptoms are of great value in the diagnosis of the nature of headache, but in taking the history of a patient, and especially of a nervous one, we must bear in mind that our suggestive way of inquiring about the nature of symptoms may mislead the patient as well as the physician. Very often our preformed idea of the patient's ailment induces us to put before him a certain number of questions whose positive answer would correspond to the general symptomatology of the already performed diagnosis. On this subject there is present in my mind the lapsus of diagnosis made by one of the most eminent neurologists of the present times, in which a case of pellagra was the object of two brilliant lectures held in the amphitheatre of a well-known European clinic, on the subject of tumor cerebellaris. The eminent neurologist, taking as a starting point of diagnosis the presence in the patient's history of the symptom "retropulsion," and forgetting completely the fact that no other manifestation could warrant such a diagnosis, demonstrated in the most convincing and scientific manner that the patient was suffering from a tumor of the cerebellum. All his assistants and many of the students had already made the diagnosis of pellagra. The patient died and the post mortem ended the controversy, proving that also in diagnosis the motto "surtout pas trop de zèle" deserves some consideration.

Returning to our argument on the subjective symptoms of headache, we must establish whether the headache is characterized by sharp boring pains, by a sensation of heaviness and dullness, by one of constriction, by a throbbing or a pulsating sensation, by a sensation of heat or a sensation of cold, etc. At present a patient is coming to my office suffering from severe headache, in which the warning symptom of the coming cephalalgia is given by an intense sensation of cold in a localized spot of the skull—the bregma. This sensation precedes generally by three hours the appearance of the headache.

Concomitant Symptoms.—An intelligent knowledge of the symptoms accompanying headache will enlighten us regarding its pathogenesis. Vomiting is one of the main symptoms that may accompany it. It may exist with or without nausea, it may appear on an empty stomach or during digestion. When

it appears on an empty stomach, without nausea and without gastric crisis, it is logical to ascribe the headache to intracranial lesions as inflammation of the meninges, neoplasm of the cerebrum or cerebellum, brain abscess, etc. The suspicion will become an assured fact when on ophthalmoscopic examination we detect the characteristic signs of papillitis or neuroretinitis. The ophthalmoscopic examination in cases of persistent cephalalgia, when giving evidence of affections of the papillæ and retinæ, will exclude the diagnosis of *Pseudomeningitis hysterica*, a functional disturbance giving a syndrome similar to that pertaining to many intracranial affections with anatomical basis.

The question arising at this point is: Is it necessary for the physician in general practice to become acquainted with the use of the ophthalmoscope? There are things in our medical curriculum whose importance varies according to circumstances. To a physician practising in a great center, the deficiency in the knowledge of ophthalmoscopy will be of very little consequence, and it will not in any way affect the patient's chances of recovery, because of the possibility of referring the patient to the oculist, and of obtaining from him the necessary information; but to the physician living remote from large centers, the ignorance of ophthalmoscopic procedures may be of consequence both to him and to the patient; to him because of his assuming a serious responsibility when treating the patient without the surety of his real conditions, and to the patient himself, because of his being compelled to undergo heavy expense in order to consult a specialist far from home, when such an expense could have been avoided were the physician skilled in ophthalmoscopy. But aside from this, the point on which we must all agree is in the necessity of every practitioner knowing how to interpret an ophthalmoscopic finding reported to him by the eye specialist.

Remaining on the argument of papillitis and neuroreninitis, I consider it of great importance for the physician to know the exact value of such symptoms. Von Graef was the first to notice the frequency of papillitis in cerebral tumors and considered the condition the result of an increased intracranial pressure. The intracranial pressure *in toto* would produce a partial compression of the sinus cavernosus. As a result of the compression a stasis of the ophthalmic vein and of the vena centralis retinæ would follow. Thus we see the cause of the headache is the same as that of papillitis and neuroretinitis. The hypothesis advanced by Von Graef was discussed and disputed by Seseman, Wolfring, Quinke, *et al.*, but the etiological factor remained the same. Intracranial pressure is the cause of papillitis and Manz demonstrated experimentally that by injecting water or defibrinated blood in the cranial cavity of a rabbit he could produce hyperemia and tumefaction of the papillæ. Knowing, therefore, the pathogenesis of papillitis, it is easy to understand that papillitis may exist in any condition producing an increase in the intracranial pressure, such as cerebral congestion, aneurysm of the internal carotid with secondary edema of the sheath of the optic nerve, meningitis basilaris, in pachymeningitis hæmorhagica, and trauma. In rare cases papillitis may exist in brain abscess and in softening of the brain. If the papillitis is unilateral it is logical to ascribe it to orbital tumor.

The process is very seldom limited to the papillæ; generally the retinæ become involved, the affection consisting in a more or less extensive clouding, venous hyperemia, hemorrhage, and the appearance of white patches near the macula lutea in the shape of small points, analogous to those seen in albuminuric retinitis. Von Graef named this condition "neuritis descendens" because of its proceeding from the brain towards the eye. Neuroretinitis may be unilateral, and when it is bilateral does not affect the eyes in the same degree. We find the neuroretinitis associated with processes at the base of the brain, and as small tumors pressing directly on the chiasm, and acute basilar meningitis, especially of a tuberculous nature. Noyes observed descending bilateral neuritis in acute myelitis. We must not forget that neuroretinitis is present also in syphilis, in lead poisoning, in alcoholism, in influenza, in malaria, in diabetes, etc. The visual power in both papillitis and neuroretinitis may be affected, but the visual symptoms are very deceptive if taken as the only indication for the ophthalmoscopic examination. In papillitis due to presence of a cerebral tumor the power of vision and the sense of color remain sometimes perfectly intact at the beginning of the pathological process. In neuroretinitis the power of vision, owing to the participation of the retinæ in the process, is more markedly affected than in papillitis, and so it is apt to be present from the very beginning of the pathological process.

Hemicrania.—If the cephalalgia should appear periodically with intervals of days, weeks, or months, being localized to one-half of the head, accentuating itself in one-half of the forehead and accompanied by nausea or vomiting, gastric crisis, photophobia, vasomotor disturbances, etc., it will be logical to make a diagnosis of hemicrania.

If this unilateral cephalalgia lasts from minutes to hours and is accompanied by scotoma scintillans, transitory hemianopsia, sharp pains in the eyeballs radiating to the temples and neck and accompanied sometimes by nausea and vomiting, the condition is *ophthalmic hemicrania.*

If with the pains and disturbances of vision there are also vertigo with palpitation, transitory paresis of the limbs of the painful side, or transitory aphasia, the case is one of *hemicrania opthalmica comitata* (Charcot).

If during the attack of hemicrania we have total paralysis of the third pair of the affected side, and sometimes of both sides, the case is one of *hemicrania ophthalmoplegica unilateralis or bilateralis.* It is important to remember that hemicrania is in such direct rapport with the epilepsy as to constitute in certain cases a real epileptic equivalent, the attack of hemicrania being substituted by an epileptic one. It is also important to know that hemicrania ophthalmica can develop transitory psycopathic forms known as *disphrenia hemicrania transitoria.* Finally, hemicrania represents one of the most serious symptoms of the premonitory stage of progressive paralysis (Meynert).

If the headache is always present during the daytime, and is characterized by a sensation of diffused intracranial tension in "helmet" form, or with localization in the occiput, growing worse during mental strain, diminishing toward evening, and disappearing at night so as to allow the patient a long and peaceful sleep, in all probability we are in presence or *neurasthenic cephalalgia.*

If the cephalalgia is accompanied by nausea, vomiting, drowsiness, asthmatic attacks, amblyopia, polyuria with low specific gravity with or without albumin, we must ascribe the cephalalgia to uremia.

When the patient is anemic and we can exclude every other cause and the cephalalgia is persistent, generally frontal, accentuating itself in the standing position and after mental strain, the diagnosis of *anemic cephalalgia* is probable. We must remember at this point that the dyscrasic condition of the blood

constitutes one of the main factors in the etiology of nervous diseases. The nervous disease is a process of reaction of the organism against improper blood supply. "The future of medicine belongs to hematology." This was the warning given a few years ago to the seekers of medical progress by one of the most eminent hematologists of our days. My belief, notwithstanding the lack of our deeper knowledge of hematology, is that, "In the blood we find the causes or the effects of disease in general, and we must in consequence look upon the conditions of the blood in every pathological condition of the organism, not only as the key to diagnosis but as the element to be principally considered in the adoption of therapeutic measures."

Abnormal conditions of the stomach, liver, uterus, and annexes, etc., but especially lesions of the nasal mucous membranes, of the middle ear, and of the pharynx, may cause severe headache. The so-called *cephalalgia pharyngotympanica* (Legal) is a very severe cephalalgia, paroxysmal in nature, the pain being principally localized in the temporo-occipital region, and easily differentiated from other forms of neuralgia because of the presence of a painful occipital point, with pains affecting the occipital, the supraorbital, and the temporal branch of the subcutaneous malar nerves. The cephalalgia pharyngotympanica is caused by catarrh of the pharynx or of the middle ear. In cases of this nature simple insufflation of the middle ear is sufficient to cure entirely the headache.

We notice also a cephalalgia affecting weak and nervous young people. Some writers speak of it as *cephalalgia adolescentis*. I consider this form of headache as one related to both the anemic and the neurasthenic headaches, and in such cases I lay special attention on two probable etiological factors, viz., masturbation and excessive mental occupation.

I have noticed sometimes very obstinate headaches appearing in people when compelled to live away from home. At the beginning I was inclined to consider the headache as due to the change of the climate, but I have been compelled to look upon the matter in an entirely different way. A persistent headache has been noticed to appear in recruits from Sardinia (Italy) when compelled to leave the island in order to serve in the army. It was noticed that on the recruit returning to his native land the headache and many other abnormal physical conditions would disappear. But this discovery could not be utilized in therapy in a country where the military service is compulsory and where the mission of the army is to amalgamate the elements of the various Italian provinces, so different one from the other in traditions, tendencies, political aspirations, and patriotic conceptions. By mere chance the observation was made that when a few of these soldiers from Sardinia were allowed to be together in the same company, to eat together, to sleep in the same ward, and to go on duty together, this condition would pass. Since then, in regiments receiving recruits from Sardinia, the rule followed is to keep the men together as much as possible and, if possible, to put them under the command of non-commissioned officers also from Sardinia. I had last year, as a patient, a lady from Texas, who was suffering from intense headaches, appearing always while she was in New York. The patient, a very intelligent woman, confessed to me without hesitancy that while in New York she always felt homesick, and that she despised the place because it was devoid of that free, generous, and warm-hearted western atmosphere where she had lived all her life and where she had all her friends and her husband. She told me that while in Texas she was always well and was troubled with headache only when in New York. I considered her case at the time as one identical to the above-mentioned. No other explanation would justify as well such a condition. I would suggest for such a form of cephalalgia the term *nostalgic headache*.

The majority of writers talk about a toxemic headache as the headache resulting from the introduction into the blood of poisons of many and diverse description. I consider such a denomination quite useless, for the reason that almost all headaches are produced by the absorption of toxic products. We can designate by this term the headaches of fevers, bilious headaches, dyspeptic headaches, the headache of gout, of rheumatism, of malaria, of lead-poisoning, that from inhalation of sewer gas, etc. So I think it would be more suitable to give a well-defined denomination to the different forms of headache, taking as a base of such denomination the pathological condition presumably causing it. To insist upon such a question may be considered somewhat academic, but in my estimation the fact of training ourselves in making under all circumstances a causal diagnosis of headache would also induce us to give more consideration to our therapeutic measures. The causal diagnosis in the pathology of diseases sinemateria has the same value that the anatomical diagnosis has in diseases having an organic base. The training of thought constitutes the foundation of medical science. Diagnosis is a work of synthesis. We all can detect symptoms; the real difficulty consists in correlating them as causes and effects. So for the vague and imperfect diagnosis of toxemic headache I would substitute, according to the causes, the terms cephalalgia alcoholica, intestinalis, saturnina, oxicarbonica, malarica, etc.

From the above description it is easy to see that the clinical significance of the symptom headache is as multiform as its pathology.

As a natural consequence its treatment constitutes one of the most complex questions of therapeutics. As the success of the general practitioner depends very largely upon the ability and resource which he exhibits when confronted with the so-called minor ailments which affect mankind, it is easy to understand that the treatment of headache constitutes for him one of the elements measuring in some degree his success or failure. The standard of our success in the treatment of headache is given by the expedition with which we relieve the patient. But we shall do better to educate our patients not to expect to be immediately relieved, but to realize and understand instead the conditions causing the ailment, and in advising them to undergo the rational hygienic and therapeutic course best adapted to the case, and to considering success not so much the speed with which our results are obtained as their permanency.

175 West Seventy-second Street

Multiple Warts.—Cooper (*British Medical Journal*) reports the cure of multiple warts by taking lime water internally. He came upon this accidentally by taking lime water, a wine-glassful before meals, for digestive disturbances. At the end of two weeks a wart on his thumb which had resisted local treatment disappeared. He tested other cases with marked success. The warts generally disappear in from four days to six weeks. He administers it in milk. Hall reports in the same periodical that warts may be cured by active purgation extending over two months. Sulphate of magnesia and aloin have both been tried with success. In one case reported there were 367 present on one hand and wrist alone.—*Mobile Medical and Surgical Journal.*

THE RELATIONSHIP OF THE LIFE INSURANCE COMPANY TO THE APPLICANT SHOWING GLYCOSURIA.

By T. STUART HART, A.M., M.D.,

NEW YORK.

INSTRUCTOR IN PHYSICAL DIAGNOSIS, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, ASSISTANT PHYSICIAN TO THE VANDERBILT CLINIC, VISITING PHYSICIAN TO THE SETON HOSPITAL.

THE problem of the applicant for life insurance who is suffering from glucose in the urine presents itself in a double aspect.

From the standpoint of the life insurance company it is only fair and right that in its position as agent for its policyholders it should carefully guard their interests by refusing to incur extra risks in cases of real persistent glycosurias and diabetics. Reports of several English companies state that diabetes represents from one to two per cent. of all their death claims.

From the standpoint of the applicant it is his right to obtain an insurance policy after passing the necessary examinations prescribed by the particular company; but it is equally his right to have these examinations conducted in a thorough and competent manner, and if his application is refused on account of an inaccurate report from a careless or incompetent examiner it is a gross infringement of his personal rights.

I am led to these observations by the very large number of patients who have told me that their first intimation of an abnormal condition of their urine came when they presented themselves as applicants for life insurance. In most of these instances the applications were refused, with perfect justice, but to a certain number of those rejected a real injustice was done, owing to the improper methods employed in the examination of the urine, or to the failure to recognize the transitory and harmless nature of the accidental finding. Some of these patients have not only been denied the benefits of insuring their lives, but have also been started on an unnecessary and actually harmful course of antidiabetic treatment and have been subjected to the worry and anxiety of believing that they were subjects of an annoying and serious disease.

First of all, then, it is necessary, as a matter of right and justice both to the insurance company and to the applicant, that the existence or nonexistence of a glycosuria should be accurately determined. It is needless to say that the urine of every applicant should be examined for glucose.

A quite common fallacy is one which depends upon the erroneous statement found in a number of textbooks to the effect that urine of a low specific gravity never contains glucose. As has been pointed out in another place (The Rational Treatment of Diabetes Mellitus, *New York Medical Journal*, September 15, 1906), I have seen many instances in which glucose was present in urine with a specific gravity under 1018, and in one with a specific gravity of only 1006 glucose could be positively identified. Another erroneous view, but I believe even more widely held, is that the reduction of Fehling's solution demonstrates the presence of glucose. I have records of several persons who were refused life insurance because the urine reduced Fehling's solution, yet these urines, although containing a reducing body such as glycuronic acid, uric acid in excess, or pentose, did not contain a pathological amount of glucose.

What, then, are the methods we should employ for the detection of glucose? If one reads over the various textbooks and monographs on this subject he is bewildered and perplexed by the great number of tests presented to him, and while as a rule many tests are described, attention is rarely directed to the amount of labor required by any given one, or the substances which may be present and vitiate its value.

It is to-day an established fact (Pavy: Carbohydrate Metabolism and Diabetes, London, 1906, p. 12) that normal urine contains a trace of glucose. This is so small in amount that it responds only to a very delicate test. It is obvious that for the purpose at present under discussion our tests should be delicate enough to detect glucose if present in abnormal quantities, but should not confuse us by demonstrating the trace normally present. Another element to be considered is the time required for the examination, and those tests should be selected which, with all due regard for accuracy, can be applied with the least expenditure of time. Our methods must be simple, but accurate, reliable, and to the point. Accuracy and reliability and speed in application of even simple tests depend to a very large degree on one's familiarity with the reaction, and one must use a given test many times before he can recognize all the finer details with the meaning of slight variations.

Having the above objects in view and having familiarized myself with most of the tests recommended for the detection of the various carbohydrates of the urine, I have come to use the following tests as a routine for the detection of glucose. The reactions are described in detail, because the conclusions reached are based upon the supposition that the reactions are conducted in the exact manner here laid down. Although the reasons are not given in detail, the methods described are the results of many little points observed in a long series of examinations (the work covers a personal experience in the examination of something over 20,000 specimens of urine), and I believe a variation from the method will lead either to inaccuracy or to a loss of time.

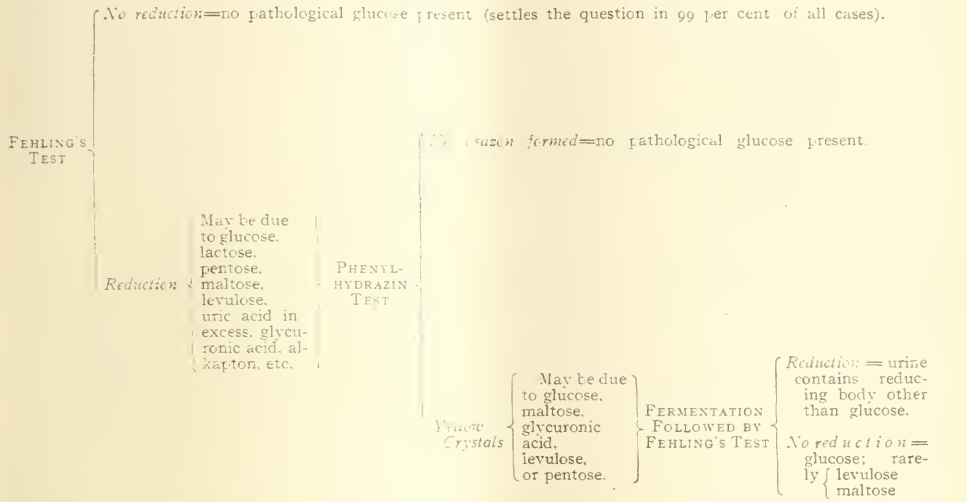
The first test which I use is *Fehling's*, applied in the following manner:

Two solutions are kept in separate bottles (if kept mixed they are apt to deteriorate), one, the copper solution, consists of 34.64 grams of crystallized copper sulphate dissolved in 500 c.c. of distilled water; the other, the alkaline solution, is made by dissolving 173 grams of potassium and sodium tartrate and 125 grams of potassium hydrate in 500 c.c. of distilled water. In a large test tube we place 1 c.c. of the copper solution, 1 c.c. of the alkaline solution, and 2 c.c. of distilled water. This is mixed and thoroughly boiled, noting that no reduction of the copper takes place. To this we add 2 c.c. of the urine to be tested,* and the whole is thoroughly boiled and the mixture then allowed to stand. If at the end of three minutes the original blue color of the mixture is unchanged an abnormal glycosuria is not present. If, however, there is any change of color to a green, yellow, or red, it indicates that some reducing substance is present in the urine; this may or may not be glucose, even a bright yellow precipitate does not neces-

*The urine must not be boiled before adding to the Fehling's solution, for many urines so treated will produce a slight reduction of Fehling's solution. An exception may be made in testing albuminous urines when the albumin must be removed by filtration after boiling and the addition of acetic acid before the application of Fehling's test. Any reduction after such procedure should be further investigated by means of the test hereafter described.

sarily indicate the presence of glucose. To such a urine further tests must be applied, as the reduction may be due to glucose, levulose, lactose, or pentose; uric acid, creatinin, or xanthin in excess; glycuronic acid following the administration of morphine, chloroform, chloral, camphor, salicylates; chloroform used as a preservative, etc.

in a warm place (99° F.) for twenty-four hours. At the end of this time, if the suspected urine contains a fermentable sugar, this tube will show a gas bubble larger than that found in the control tube. The suspected urine which has been fermented should then be retested with Fehling's solution; if no reduction then occurs it is positive evidence that



No reduction=no pathological glucose present (settles the question in 99 per cent of all cases).
Fehling's Test
Osazon formed=no pathological glucose present.
Reduction
May be due to glucose, lactose, pentose, maltose, levulose, uric acid in excess, glycuronic acid, alkapton, etc.
Phenylhydrazin Test
Yellow Crystals
May be due to glucose, maltose, glycuronic acid, levulose, or pentose.
Fermentation Followed by Fehling's Test
Reduction = urine contains reducing body other than glucose.
No reduction = glucose; rarely levulose maltose

Any urine which reduces Fehling's solution should be subjected to the *phenylhydrazin test*. The simplest way of applying this test is as follows: In a large test tube we place 5 drops of pure phenylhydrazin, 10 drops of glacial acetic acid, and 1 c.c. of a saturated solution of sodium chloride; to this is added 6 c.c. of the urine to be tested. This mixture is boiled for about two minutes, or until the fluid is evaporated to one-half of its original volume. The test tube is then set aside and allowed to cool slowly (rapid cooling is to be avoided); if the test is positive, bunches of long feathery yellow osazon crystals separate and may be readily recognized under the microscope with a one-fifth objective. If a large amount of glucose is present the crystals form in two or three minutes, but when only a trace is suspected it is better to allow the test tube to stand for twenty-four hours before examining the sediment. The crystals only are characteristic, the dark yellow globules, sometimes covered with spicules, are not of diagnostic value. The absence of the characteristic crystals after standing for twenty-four hours assures us that a pathological glycosuria is not present. A positive finding may be due to glucose, levulose, maltose, or pentose. Lactose and glycuronic acid each form an osazon under certain conditions, but not in the quantities found in the urine when the test is conducted in the manner described above. Uric acid, creatinin, xanthin, dextrin, alkapton, and chloroform do not form osazons.

A urine which reduces Fehling's solution and forms osazon crystals with the phenylhydrazin test should be tested by *fermentation*. This is most easily conducted in the Einhorn fermentation tubes. Ten c.c. of the urine is shaken up with a piece of fresh yeast (the ordinary compressed yeast cake), the size of a large pea, and put into the fermentation tube, filling the closed upright tube and being careful to expel all air bubbles. A similar control tube is prepared with yeast and a urine which does not reduce Fehling's solution. Both tubes are placed

the suspected urine contained sugar which has been broken down by fermentation. The only fermentable sugars found in the urine are glucose, levulose, and maltose. Pentose does not ferment; lactose does not ferment with ordinary yeast. Maltose is extremely rare, and I have met with it in urine only on one occasion. It may be distinguished by its greater rotation than glucose and by its failure to react to Barford's reagent.* Levulose may be distinguished from glucose by its negative rotation when examined in the polariscope and by giving a positive Seliwanoff reaction.*

The application of these three tests, Fehling's, the phenylhydrazin, and the fermentation, to a suspected urine requires about ten minutes of one's time on one day and five minutes more twenty-four hours later.

If it be objected to this scheme that it is somewhat long and cumbersome the reply is that the negative Fehling's test will settle definitely a very large percentage of all the cases, and the small number of doubtful cases are in all fairness entitled to the benefit of the doubt as to whether sugar is present until the other tests have been applied.

URINES REDUCING FEHLING'S SOLUTION BUT CONTAINING NO GLUCOSE

Name	Specific gravity	Reaction	Sugar: Albumin	Sugar: Fehling's	Sugar: Phenylhydrazin	Sugar: Fehling's after Fermentation	Reduction Due to—
A. F. B...	1032	ac.	O	+	O	+	Chloroform used as a preservative.
M. G....	1015	ac.	tr.	+	O	+	Glycuronic acid.
P. B. D.	1019	ac. +	O	+	O	+	Lactose.
J. F. M...	1028	ac. +	O	+	O	+	Uric acid.

URINES CAUSING ONLY A VERY SLIGHT CHANGE OF COLOR ON APPLYING FEHLING'S TEST, BUT WHICH CONTAIN GLUCOSE

			Sugar				
Name	Specific gravity	Reaction	Albumin	Fehling's	Phenyl hydrazin	Fehling after Fermentation	Diagnosis
H. A.	1005	ac.	tr	+	+	0	Diabetes [illegible]
H. L.	1009	alk.	+	+	+	0	"
H. W. R.	1014	ac.	tr	+	+	0	" acetone present
M. K.	1018	ac.	+	+	+	0	Nephritis with glycosuria.
J. S.	1012	ac.	0	+	+	0	Diabetes and Basedow's.
E. R. W.	1021	ac.	0	+	+	0	Diabetes and obesity (acetone present)
G. C. H.	1023	ac.	0	+	+	0	Diabetes mellitus
S. K.	1017	ac.	0	+	+	0	Glycosuria (transient).
M. W.	1012	ac.	0	+	+	0	"
J. D.	1011	ac.	0	+	+	0	Diabetes mellitus

The above tabulations illustrate a few of many instances in which a series of tests have been of value in determining the presence or absence of a glycosuria.

As an instance of the injustice and harm done by inadequate chemical tests I may recall the following case. A young salesman, twenty-eight years old, applied to one of our large life companies for insurance. His history and physical examination were satisfactory, but a policy was refused on the ground that he had glycosuria, and he was referred to his family physician for further advice. After some months of treatment for his "diabetes," he was brought to Dr. E. G. Janeway for further advice, and while under observation it was my fortune to watch the patient and make a number of examinations of his urine. His urine constantly gave a slow but definite yellow reduction to Fehling's fluid, also readily demonstrable phenylhydrazin crystals, but failed to ferment with yeast, neither producing gas nor ceasing to reduce Fehling's solution after attempts at fermentation. It was plain that the reducing substance in this case was not glucose, and further investigation with the polariscope, the orcin test, the melting point of the osazon, etc., identified this reducing substance as pentose. Following the administration of 100 grams of dextrose in a single dose, no glycosuria could be discovered.

Here, then, was a man who was refused insurance on his life, worried by the thought that he was the host of a serious disease, and subjected for months to the discomforts and positive evils of a "diabetic diet," merely because his examiners, by neglecting the use of one or two simple tests, failed to recognize that he was the subject of an interesting but perfectly harmless anomaly of metabolism.*

It is a fact well known by insurance examiners that occasionally dishonest men who know that they are suffering from diabetes will prepare themselves for examination by a course of rigid diet in order to avoid the detection of glucose. This probably succeeds so rarely that the aggregate loss to the insurance companies is comparatively insignificant.

There are, however, methods by which these fraudulent attempts may be thwarted. One of these is the routine examination of the urine for the acetone bodies. As I have pointed out in another place (*American Journal of the Medical Sciences*, August, 1906), the withdrawal of carbohydrate food from a diabetic is usually followed by a persistent excretion of acetone and diacetic acid in the urine.

If Legal's, Arnold's, and Gerhardt's tests were used in the routine examinations of the urine few diabetics would escape detection. The detection of acetone or diacetic acid in the urine does not necessarily mean diabetes, for they are found in many other conditions, such as starvation, pregnancy, following operations, and the administration of drugs, such as benzol, morphine, antipyrin, etc. Such a discovery may, however, put us on the right track. Our next step should be to determine our patient's tolerance for glucose. This is best done in such a case by having him take in our presence 100 grams of glucose in 250 c.c. of water on an empty stomach, and examining all the urine passed in the succeeding hour or two. A man of normal assimilative powers will pass through this ordeal with a urine free from glucose, but the presence of a glycosuria will indicate that his tolerance for carbohydrates is below the normal.

This aspect is illustrated by the following case:

E. W. P., a merchant, thirty-two years of age, applied for life insurance and passed a satisfactory examination with the exception that in two trials the examiner had found a very small amount of glucose in his urine; on a third test the urine was found to be free from glucose. Pending the consideration of his application he was advised by the life insurance company to place himself under my observation in order that he might obtain my report for further guidance. When he consulted me he gave me the above facts and wished me to examine his urine and make a report of my findings which he could present to the company. I questioned him about his diet, which he recounted to me in detail for the preceding twenty-four hours, and which, according to his statement, consisted of an ordinary mixed diet with no inconsiderable amount of carbohydrate food. I tested both a mixed specimen which he had brought with him, and also a specimen passed in my presence. Both were absolutely free from glucose. On applying Legal's and Arnold's tests a small but abnormal amount of acetone and diacetic acid were found to be present.

He was at once given three ounces of dextrose in eight ounces of water. The urine passed in my presence an hour later contained a large amount of glucose.

Subsequent observation and confession demonstrated that this patient was suffering from a true diabetes of medium severity, but by systematic and careful dieting he could keep his urine free from glucose for long periods. I recently learned that he decided not to submit my report to the life insurance company, and had withdrawn his application for insurance.

Having settled the question as to whether a glycosuria really exists, it is fair to ask whether there are not some cases of glycosuria which are good risks for life insurance. This is doubtless open to debate. In my own opinion I do not believe that any case of real diabetes, no matter how mild the type, is a good risk. The reasons for this opinion are that an accurate prognosis in mild diabetes, with its liability to develop serious complications, is exceedingly difficult. It is well to remember, however, that glycosuria and diabetes are not synonomous. Glycosuria may be quite transient, as, for example, when it follows a febrile attack, such as influenza, etc., or as occasionally is seen after moderately severe exercise, or again, after slight injuries to the scalp.* Glycosuria is also frequently seen in persons who have just partaken of a large amount of saccharine food. It is probable that

This case was reported in detail by Dr. T. C. Janeway in the *American Journal of the Medical Sciences*, September, 1906.

*Higgins and Ogden, *Boston Medical and Surgical Journal*, February 28, 1905.

everyone has a definite limit to his tolerance for sugars, but glycosuria cannot be produced in a healthy individual by the ingestion of starchy food, even in excess (von Noorden*), and a healthy man should be able to take 100 grams (3 1-3 ounces) of dextrose on an empty stomach without showing a glycosuria. An insurance company is justified in regarding with suspicion an applicant who has once shown a glycosuria, but such a one who is able to take the above test meal of dextrose without excreting glucose in his urine is entitled to have this suspicion forgotten.

Another class of cases in which glycosuria is a common finding are the obese. Sir Hector Mackenzie says that glycosuria may be observed in about a third of all cases of marked corpulency. These applicants would probably be refused because of their overweight, but it is worth while noting, contrary I believe to the commonly accepted idea, that in these cases the prognosis is not very good, and such statistics as I have been able to obtain indicate that the underweight cases are the better risks.†

Glycosuria may, of course, be associated with other conditions which independently render the subject a poor risk; such, for example, are diseases of the liver, of the central nervous system, and of the kidneys. In gout glucose in the urine is usually transient and unimportant.

Among other factors which may influence one's estimate of the probable risk are the following:

Race.—The Hebrew race seem to be particularly prone to this disease.

Family History.—According to Williamson thirteen per cent. of diabetics show that some other members of the family have suffered from this disease.

Occupation.—"The insuring classes are affected with diabetes to a much greater extent than the working classes." (Mackenzie.)

Age.—Other things being equal, a glycosuria after thirty-five years of age is much less likely to be a serious matter than one occurring under this age.

Until extensive statistics bearing on this question are at our disposal, it will be impossible to lay down general laws, but I am personally firmly convinced that many of those who have once shown a glycosuria, when individually considered, may be selected as perfectly good risks.

Conclusions.—1. The life insurance company owes it to itself and to the applicant that a diagnosis of glycosuria should be carefully and thoroughly made.

2. The presence of a slight glycosuria cannot be positively asserted on the strength of one test.

3. The following tests applied as described above and in the following order is the shortest accurate method of ascertaining the presence or absence of glycosuria: (*a*) Fehling's test, (*b*) phenylhydrazin test. (*c*) fermentations followed by Fehling's test.

4. Many attempts to hide a persistent glycosuria by self-restricted diet may be detected by the routine use of tests for the acetone bodies.

5. No true diabetic is a good risk for life insurance.

6. Certain cases of transient glycosuria may be perfectly good risks. In studying such cases the race, family history, occupation, age, and weight all have a bearing and should be considered, together with individual tests for the acetone bodies and the use of a test meal of 100 grams of dextrose.

*Von Noorden: *Diabetes*, New York, 1905, p. 33.

†Transactions of the Life Assurance Medical Officers' Association, London, 1902-1903, p. 60.

The Colon—A Strategic Point in Medicine.—Dunning S. Wilson treats as synonymous the terms colon and large intestine. There is no practical difference in their structure or function. The function of the large intestine is twofold. It serves as an absorbent of the material occupying its lumen as well as playing the part of sewer. The writer explains his use of the word strategic by saying that this point may serve admirably in fighting disease, but unless it is taken care of and watched closely it may prove even in health to be the cause of death. He quotes Metchnikoff, who believes that the colon and other parts of the large intestine are responsible for the low average of human life. In order to put this large gut into a condition as nearly harmless as possible, the writer suggests the following measures: Plenty of pure water should be drunk. This will aid in the elimination of phenol, indol, and the like. The use of milk which has undergone lactic acid fermentation greatly reduces the products of intestinal putrefaction. The careful use of an occasional saline laxative will flush the whole intestinal canal. Finally, the writer advises the regular employment of colon lavage, which cleanses the large intestine as nothing else will do. He believes that such diseases as perityphlitis, appendicitis, dysentery, and certain forms of fevers of the typhoid type can be prevented by simple measures, which keep the colon comparatively clean. He believes, too, that headaches would be less frequent, neuralgia could be cured, and gout would be robbed of its sting if patients could be persuaded to follow a few simple rules.—*The American Practitioner and News.*

On the Theory of Natural and Artificial Feeding in Infancy.—Franz Hamburger, in discussing the difference between albuminous bodies of different kinds of animals, states that the caseins of human and cow's milk, while they possess the same chemical elements, have a different chemical structure, as is shown by biological experiments. Their biological action on the living animal is not the same. Proteid bodies, while corresponding to each other, may have different biochemical structures. The writer believes that the chief difference between natural and artificial nourishment consists in the difference in the proteids in human and cow's milk. It is said that cow's proteid is changed into the human proteid in the intestines. The intestinal cells during infancy are not mature enough to take up the work of digestion, so they react to other than human albumen as if to a poison. This unaccustomed work is bad for the tender intestine, and offers one of the chief disadvantages of artificial nourishment. It has been proved that the antitoxins of human milk may cross over into the tissues of the nursling, while those of another kind do not. However, a proteid of another kind can go over into the tissues of an infant during the first days of life apparently unaltered. In artificial feeding assimilation differs theoretically from that of breast feeding, the one compelling the child to transform bovine casein into that of the human, while the other merely alters the maternal proteid into that of the infant. Much remains to be done by means of experimental investigation in this field. The writer concludes that it is more than likely that it will never be possible to make any artificial nourishment equal to that of breast milk.—*Archives of Pediatrics.*

Treatment of Pneumothorax.—Morphine or other sedatives may be needed to relieve pain, and sometimes even chloroform may be necessary. Stimulants, too, are usually required. Cupping the chest, or even venesection, is particularly useful when there is much cyanosis. The removal of the air is needed when there is great distention and consequent dyspnea. A fine trocar should be introduced and the air be allowed to escape. Anything in the shape of aspiration would probably reopen the wound in the pleura, and more air would thus pass into the pleural cavity.—*The Hospital.*

INTRATRACHEAL INJECTIONS IN THE TREATMENT OF CHRONIC DISEASES OF THE LUNGS.

At the present time physicians are pretty well agreed that the chronic diseases of the lungs with tuberculosis at the head of them are best treated by placing the affected individuals in the most favorable physical surroundings, by providing them with good food, pure air, physical rest, and equable mental life. Thus only the natural defences of the organism are put in the best conditions for attacking the bacterial invaders of the lungs and for nullifying their toxic products. But to prescribe good food, pure air, and physical rest to the majority of our clinic patients is to ask of them the impossible. Tuberculosis, it is true, spares the rich man no more than the poor, but while the former has every means at his command of fighting the dread disease, the latter is usually compelled to carry on his daily avocation, every new phase and symptom of the disease making the exercise of it more and more difficult. Symptomatic treatment aimed at the alleviation of the more disturbing factors can never, therefore, be banished from the therapeutics of the chronic disease of the lungs, and every new means of such treatment must receive the careful consideration of the modern practitioner.

In this connection it has always been the problem to attack the lungs directly, for many symptoms, such as cough, dyspnea, etc., are due more to the local conditions than to the general intoxication of the organism. Inhalation of drugs in the state of very fine division has met with some success, especially in the practice of throat and nose specialists, and many years ago, in 1853, Dr. Green of New York originated the method of intratracheal injections. At the time the New York Academy of Medicine frowned upon this plan, as offering great difficulties in technique and many possible dangers for the patient. Since then, however, Reichert and Jacob, Mendel, Massei, and many others, have used the method with some success. In a dissertation dealing with the subject in *Russkii Vratch*, No. 26, 1907, Dr. Galebsky considers the method again, and brings much experimental evidence to show its superiority over inhalations. The author studied three phases of the problem experimentally, namely, the effect of such injections upon animals, the parts of the lungs reached by the liquids used, and the character of the reaction, if any, set up in the lungs. The dogs experimented upon stood the injections very well, the amount used reaching 30 c.c., introduced by means of a modified Pravaz syringe, 5 c.c. at a time. In using eucalyptol and menthol it was possible to show that the drugs reached the alveoli of the lungs, while the direction of penetration could be easily controlled by placing the animal on one or the other side for some minutes after the injection. Oil of sweet almonds and salt solution produced hardly any reaction, while eucalyptol and menthol, which later were used on patients, in dogs produced some slight changes, such as mild catarrhal reaction and the appearance of some granulation tissue in the interalveolar spaces. The method was then applied in the treatment of seventeen patients, fourteen of whom were suffering from tuberculosis, two had putrid bronchitis, one simple bronchitis, and one suffered from bronchiectasis with beginning gangrene of the lungs. The patients were always placed in the position for laryngoscopy, and the point of the syringe was introduced beyond the vocal cords under the control of the mirror. Cocaine used in the first injection was dispensed with later on, and the drugs used—chiefly eucalyptol and menthol—were introduced dissolved in sweet almond oil. The patients were then placed on one or the other side, depending upon the localization of the disease in the lungs.

The most important effect was found in the diminution of cough, which before treatment was robbing the patients of sleep and interfering with their general wellbeing. Moreover, the alleviation of this symptom was not attained by lowering the sensitiveness of lung tissue and thus diminishing the reflex cough caused by the accumulation of material in the bronchi. Apparently the formation of the sputum was diminished, and at the same time it became thinner and was more easily expelled than was usually the case. The intolerable smell accompanying the case of putrid bronchitis soon disappeared, and the subjective condition of all the patients showed improvement running parallel to the amelioration of the physical symptoms. The physical signs showed some improvement, both coarse and fine râles being much diminished.

Galebsky believes that this method of treating local conditions in the lungs will compare quite favorably with the more usual one of inhalation. The drugs used may be brought more directly to the lungs in the amounts desired; to a certain degree their action may be localized to one or the other side of the lungs, and finally the slight sensibility of the trachea does away with such reflex symptoms as cough, vertigo, and fits of choking that are quite frequently observed in the use of inhalations with nervous patients. Moreover, Galebsky's animal experiments with subsequent pathological study apparently prove that the injected liquids reach the alveoli of the lungs, the interstitial tissue, and the bronchial glands much more surely than the drugs introduced by inhalation.

THE WELSH CANCER CURE.

ALTHOUGH this is called a hard and practical age, there was probably never a time when people were more gullible in matters spiritual and matters medical than they are to-day. In no way has this been shown more clearly than in the matter of Christian Science. This cult has gained thousands of adherents, and its professors, or rather those at the

head of this strange mixture of religion, faith healing, and materialism, have made millions of dollars, despite the fact that its uselessness in cases of serious sickness or of accident has been demonstrated times without number. However, the followers of Mother Eddy are by no means the only people who are moved by the wiles of the honest fanatic, who bases his power upon religion or on an appeal to that mysterious something which is inherent in every individual. The person who is sick unto death of an incurable disease is apt, whether he be ignorant or educated, to try any remedy that promises relief, and to believe in cures which in his rational moods he would be the first to deride.

This weakness of human nature is receiving at the present time conclusive proof of its existence in an out-of-the-way part of Great Britain. Two uneducated Welshmen living in the little town of Cardigan claim to have discovered a cure for cancer. Their claim has been accepted as genuine by thousands of sufferers who have flocked into Cardigan from America, Canada, France, Germany, Africa, and Egypt, and letters have been sent from all portions of the globe addressed to these simple men who have undertaken to accomplish that which has baffled the skill of the best minds of the medical profession for generations past. Even distant Japan has written for information with respect to the precious fluid.

These Welsh healers are brothers of the simplest type and of the most intense faith in themselves and their remedies, and, like Christian Scientists, have inspired their patients with the greatest enthusiasm and confidence. These patients are many of them in good positions, clever men of business, and women of intellectuality and standing. It appears that the cure consists in painting the affected part for an indefinite period with a fluid the composition of which is a secret to which the brothers Evans alone are supposed to hold the key. A physician has been investigating the matter recently, and has published the results; his account affords pathetic and instructive reading. The principle of the treatment is somewhat as follows: The cancer curers believe that cancer is a kind of living octopus, with innumerable tentacles attached to its body and spreading in all directions, and that this body, with the tentacles attached may be drawn to one definite focus, so that the strange creature can be extracted in its entirety. The investigator of this cure found that the fluid used was a solution of one of the strong mineral corrosives which have been used in all ages and countries, and have formed the secret remedies of quacks of every description from time immemorial. Many years ago the "canquoin" treatment for cancer was popular in America. This consisted of a paste made of chloride of zinc and flour. The remedy used by the Welsh brothers is a solution of chloride of zinc.

The results of the treatment are just what one would look for. In some cases the disease was not cancer and the patients recovered. In some cases it probably was cancer and disappeared under the destructive influence of the zinc chloride or spontaneously. In other cases the disease was certainly cancer, and the confiding sufferers, after a brief period of hope, were cruelly undeceived and went home to die.

The Procreation of Genius.

In a paper on the "Genesis of Genius," read before the recent International Congress on Psychiatry, at Amsterdam, Dr. Louise G. Rabinovitch of New York called attention to the remarkable fact that comparatively few geniuses have been the first-born of their parents. In a study of 74 biographies of great men and women—poets, writers, politicians, painters, and musicians—she found but 10 first-born. Among 42 writers and poets, but six were the eldest children; among 17 painters, but one was the first-born of his mother (he was a natural child); among 15 musicians, there were only two first-born. Not only were these men of genius not the first-born, in a very large number of cases they were the youngest or next to the youngest of the family. Thus Coleridge was the last of thirteen children; James Fenimore Cooper was the eleventh of twelve children; Washington Irving was the last of eleven; Balzac, the last of three; George Eliot, the last of four; Napoleon was the eighth, and probably the last; Daniel Webster, the last of seven; Benjamin Franklin was the last of seventeen, and the last-born of the last-born for several generations; Rembrandt was the last of six children; Rubens, the last of seven; Sir Edwin Landseer, the fifth of seven children; Joshua Reynolds was the seventh child of his parents; Carl Maria Weber, the ninth; Richard Wagner, the last of seven; Mozart, the last of seven; Schumann, the last of five; Schubert, the thirteenth of fourteen. The parents, therefore, of great men were, for the most part, of a ripe age at the time of the conception of the latter; that is to say, the cellular potentiality of the parents was then at its maximum from the mental as well as the physical point of view. Herein lies hope for Osler's superannuates who have passed the dead-line of forty years. If they can do nothing more for the world with hands or brains, they can at least strive to people the earth with men of genius, who will carry on and perfect the work which they themselves, at the acme of their usefulness, have been condemned by the Oxford professor to lay down.

Ciliated Cells Found in the Spleen.

Some time ago we commented upon the fact that microscopical structures of great value are often discovered by mere chance, citing as an instance a human Graafian follicle containing two ova that was found by Welch (Medical Record, June 22, 1907). In *Russkii Vratch*, No. 27, 1907, Dr. Kalachnikoff of the University of Tomsk reports another such finding of perhaps still greater interest; this consisted of a group of ciliated cylindrical cells seen in sections of a spleen from a patient dead of typhoid fever. In structure these cells resembled quite closely the normal ciliated cells found in the trachea; their nuclei were oval and large, taking up about one-third of the cell, while the cilia showed node-like thickenings at their origin from the distal borders of the cells. They were found in a number of sections, and apparently were arranged in cylindrical columns of different lengths, depending upon the number of elements in each group, but all of the same thickness equal to the length of one cell. Both superficial and deep sections contained them embedded in the normal tissue of the spleen; no new growth whatsoever was to be found in any of the remaining organs of the patient. The author considers that his find may serve as some corroboration of the theory of Cohnheim, holding embryonal inclusions responsible for the origin of tumors, and

calls attention to the remarkable fact that the cells in question had probably lived for some thirty-eight years, which was the age of the patient, among other cells quite foreign to them and strongly phagocytic at the same time. He thinks, indeed, that experiments with the transplantation of embryonal elements may clear up many biological problems, and especially throw light upon the origin of new growths.

Meat Eating and Cancer.

An English physician, Dr. G. Cooke Adams, has, according to newspaper reports, just concluded a two years' study of cancer in Chicago, as a result of which he has joined the ranks of those who believe that excessive meat eating is the cause of the disease. This is an old theory, one of the first indeed to be offered when investigators began seriously to search for a cause of the increase of cancer in modern times, but Dr. Adams varies it somewhat by the suggestion that it is the consumption of the flesh of diseased animals chiefly that leads to the development of cancerous growths. Some time ago Oldfield had something of the same notion, but his theory was that it was the flesh, not of diseased animals (the tuberculous, the actinomycotic, etc.), but of those which had been overfed, that favored the production of cancer. In other words, it was not autointoxication of the human, but rather that of the animal whose flesh was eaten, which gave the impetus to malignancy of cell growth. Dr. Adams's theory, if he is correctly reported, would seem to be of the same order—that the toxic principle, whatever that may be, causing the disease is present in the meat itself, and is not formed by an autotoxic process in the intestine or tissues of the consumer. Dr. Robert Bell of London holds the autointoxication theory, but does not regard meat as a special cause, except indirectly as leading to a more ready production of toxic material. Should the autotoxic theory prove to be correct, it may possibly be found that diseased meat differs from sound meat, and both from other foods, only in the fact that the elaboration of a cancer-producing substance from the former is a more rapid process, and one requiring a smaller amount of the offending food.

The Milk Supply of New York.

The Health Department of this city has sent a circular to all the dairymen and farmers who contribute to the milk supply of New York, calling their attention to certain rules in respect of cleanliness which they are expected to follow if they wish to sell their milk to city customers. The provisions of this circular are not unreasonable; indeed, they are no more than any farmer with a fairly developed hygienic conscience would follow without urging; but the opposition which they have aroused is rather disquieting to those innocent souls who have been nursing the comforting belief that the milk supply of New York is, on the whole, fairly good. The literary members of the class affected have been writing sarcastic letters to the New York papers regarding what they evidently consider counsels of perfection, to be followed only by the elect or by the elite of the amateur dairymen; those unable to wield the pen have contented themselves with ejaculatory remarks and threats to give their milk to the pigs, thereby producing a famine which will bring the New York Department of Health to terms. They probably will not, for milk is milk, and the money it brings is money, but it is not unlikely that they will demand and receive a higher price for their product. Whether the factories, which receive and distribute the milk of the small farms, or the city consumers will pay this increased cost remains to be seen; but that the consumer will get cleaner milk, if the inspectors do their duty, is certain. The milk will even then be far from ideal, but it will be fit for pasteurization. If the farmers can be reformed, there will be some hope for the Aldermen of the city, and when the latter have come to a realizing sense that the lives of the babies of the great mass of their constituents are worthy of more consideration than the pockets of a few of them, they will perhaps consent to a pasteurization ordinance. Then New York will have milk that is fit to drink and to be given to infants, and it will no longer in this respect be behind Vienna and many other cities of Europe in its care for the health of its future citizens.

The Medical Explorer.

An interesting echo of the life and work of David Livingstone occurs in *The Lancet* for September 7. A new mission has recently been established in Central Africa under the supervision of Mr. Malcolm Moffat, a nephew of Dr. Livingstone and Dr. Alexander Brown. These not long since made a journey to the spot where lie the remains of the great explorer who died in 1873. They obtained an interview with a native chief, Chitambo, who told them what he heard from his father of Livingstone's last hours. "He was sick," said Chitambo; "he was here just one day and another day. His boys built him a 'msasa' (booth or hut) under the 'mupundu' tree, and it was there that he died. His men took his body; they buried the heart and other parts, but his body they kept. They buried them under the mupundu tree; the body they dried in the sun. They stayed three moons drying the body; and the old Chitambo called the people from all the country round and they brought forth the drums, and they wailed the Engelsea. . . . . Three months his men stayed in the village, and they dried his body and put it in a box, and they tied it round and round, and Chitambo said, 'Engelesa has died here; it is his country now.' Then Engelesa's men brought forth much cloth, and gave it to the people, and they went away with the body to the North." It is certainly affecting to learn of the love and veneration which Livingstone had inspired in the minds of these natives. As *The Lancet* truly says, "Livingstone's conquests were more than those of science. They were conquests of humanity."

News of the Week.

Dr. Albert Warren Ferris of this city has been appointed by Governor Hughes as president of the State Commission in Lunacy, to succeed Dr. Charles W. Pilgrim resigned. Dr. Ferris is a graduate of the College of Physicians and Surgeons, New York, in the class of 1882.

Dr. Julius Grinker was recently appointed Consulting Neurologist to the County Hospital for the Insane and the Cook County, Ill., Infirmary at Dunning.

Seventy Years of Practice.—On August 1, Dr. William Bayard of St. John, N. B., celebrated the seventieth anniversary of his graduation in medicine from the University of Edinburgh. The members of the local medical associations took part in making the day a memorable one for Dr. Bayard, who is now ninety-three years of age, but is in good

health and recently performed an operation. At its last commencement the University of Edinburgh conferred on Dr. Bayard the honorary degree of LL.D.

A Federal Milk Inquiry.—The United States Public Health and Marine Hospital Service has taken up the milk question and is beginning by collecting data in regard to the transmission of disease by milk supplies. To this end a circular letter is being distributed which invites medical men to communicate to the Service the results of any observations bearing on the subject that they may have made. The data asked for include the date, the place, the number of cases, the mortality, the number of cases among milk consumers, the circumstances attending the outbreak, the locality in which the original case or cases occurred, the manner in which the milk was infected, and the reasons for believing that the disease was conveyed in this way.

Plague in San Francisco.—Five surgeons of the Marine Hospital Service are now in charge of the measures for combating bubonic plague in San Francisco. Twelve district headquarters have been established, from which daily reports are made for the purpose of guiding the Board of Health in its work.

Beriberi.—A bark 130 days out from Honolulu with a cargo of sugar for New York has been obliged to put in at San Juan, P. R., owing to the fact that most of the crew were incapacitated by beriberi.

Cholera.—According to despatches from St. Petersburg, up to the present 4,512 cases of cholera have been reported in the affected districts of Russia. Of this number 2,320 were fatal. The crop report of the Central Statistical Committee, just issued, shows that another year of famine is to be expected.

Famine in China.—It is now estimated that 2,000,000 persons perished by famine in Kiang-su and neighboring provinces during the first six months of this year. Owing to the excessive rainfall last summer the crops entirely failed and food is now unobtainable, with no prospect of relief.

Epileptic Colony Favored.—At a recent meeting of the Madison County Medical Society, Illinois, resolutions were presented and adopted urging that the influence of this Society be exerted in favor of establishing a State colony for the care and treatment of epileptics. One copy of the resolution was sent to the State authorities, and another to the Illinois State Medical Society for similar action.

Violent Deaths in Chicago.—The Coroner of Cook County reports that during August there were 367 deaths reported to him. Of the deceased, 31 committed suicide, 27 were killed by railroad accidents, 15 by street cars, and 13 were murdered Lockjaw caused 5 deaths; elevators, 5 deaths; illegal operations, 3 deaths; alcoholism, 14 deaths; burns and scalds, 13 deaths; drowning, 24 deaths, and electrocution, 2 deaths.

Births and Deaths in Pittsburg.—During the year 1906 there were 7,644 births reported in Pittsburg and 7,038 deaths. Up to September 1 of this year 5,386 births have been recorded and 5,475 deaths, but it is believed that this state of affairs is not due to lessened fertility of the citizens so much as to neglect of the physicians and midwives to report the births occurring under their care.

Railway Hygiene.—By order of Dr. Samuel G. Dixon, Health Commissioner of the State of Pennsylvania, porters are forbidden to brush the clothing of passengers in the aisles of railway cars. It is also required that sheets in the berths of sleeping cars shall be sufficiently long to turn over the upper end of the blanket at least two feet, so as to prevent the blanket from coming in contact with the face of the occupant of the berth.

A Cancer Exhibition.—In connection with the general meeting of the International Surgical Society in Brussels, in September, 1908, at which a discussion on cancer will take place, it is proposed to arrange a cancer exhibition, and a circular has been issued inviting contributions, not only from members of the society, but also from others. All objects connected with cancerous disease will be received, but the following classes are enumerated: (1) Macroscopic or microscopic specimens, either instructive from a surgical standpoint or of special interest on account of their localization or method of dissemination; (2) topographical anatomical specimens or drawings illustrating individual operations for cancer; (3) topographical anatomical preparations of the lymphatic vessels and glands of particular regions; (4) statistical wall charts illustrating the duration of the treatment of cancerous diseases; (5) statistical wall charts illustrating the frequency of primary cancer and its metastases in particular organs, based upon clinical or pathological experience; (6) statistical charts dealing with the spread of cancer in different countries, exact plans of so-called cancer foci, and family trees of families in which cancer has existed for several generations; plans of cancer institutions and hospitals, their reports of work done, and financial statements; (8) reports of movements to encourage the early treatment of cancerous diseases, appeals to the public, and proposals as to the means by which a knowledge of the importance of the early diagnosis of cancer may be brought home to the public without exciting panic. Communications should be addressed to Prof. A. Depage, 75 Avenue Louise, Brussels, who will take charge of the specimens, arrange them for exhibition, and return them at the close of the meeting. Exhibitors will have an opportunity of demonstrating their specimens to members during the meeting.—*British Medical Journal.*

American Hospital Association.—The ninth annual meeting of this Association was held at Chicago on September 17, 18, 19, and 20, and was attended by representatives of over 150 hospitals in twenty-four States and provinces of the United States and Canada. The Association entertained as its guests Miss Jane Addams of Hull House, Chicago, Dr. Richard C. Cabot of Boston, Hon. J. Ross Robertson, founder of the Hospital for Sick Children, Toronto, and Dr. A. J. Ochsner, author of "Hospitals: Their Organization and Management." A resolution was adopted making hospital trustees, as well as hospital superintendents, eligible to active membership. The following officers were elected for the ensuing year: *President,* Dr. S. S. Goldwater, New York; *Vice-Presidents,* Hon. J. Ross Robertson, Toronto, and Dr. John M. Peters, Providence, R. I.; *Secretary,* Dr. W. L. Babcock, Detroit; *Treasurer,* Asa Bacon, Chicago.

The Missouri Valley Medical Association.—At the annual meeting of this organization held in Omaha on September 6, officers for the ensuing year were elected as follows: *President,* Dr. W. F. Milroy of Omaha; *Vice-Presidents,* Dr. C. B. Hardin of Kansas City and Dr. A. E. Keen of Blockton, Ia.; *Secretary,* Dr. C. Woods Fassett of St. Joseph; *Treasurer,* Dr. H. B. Jennings of Council Bluffs.

Canadian Medical Association.—At its meeting held in Montreal on September 13 this organization

decided to hold next year's meeting at Ottawa. Officers were elected as follows: *President,* Dr. F. Montizambert of Ottawa; *Vice-Presidents,* Dr. F. R. England of Montreal, Dr. W. H. B. Aikins of Toronto, Dr. Alex McNeill of Summerside, P. E. I., Dr. Ross of Sackville, N. B., and Dr. M. A. Currie of Halifax, N. S.; *Secretary,* Dr. George B. Elliott of Toronto; *Treasurer,* Dr. H. B. Small of Ottawa.

Washington County (Vt.) Medical Society.—Officers as follows were elected at the meeting of this society held in Montpelier on September 10: *President,* Dr. A. C. Bailey of Randolph; *Vice-President,* Dr. M. F. McGuire of Montpelier; *Secretary,* Dr. O. G. Stickney of Barre; *Treasurer,* Dr. E. A. Colton of Montpelier.

American Electrotherapeutic Association.—At the seventeenth annual meeting of this Association held in Boston on September 19, officers as follows were elected: *President,* Dr. H. F. Pitcher of Haverhill, Mass.; *Vice-Presidents,* Dr. Edward C. Titus of New York and Dr. Jefferson D. Gibson of Denver, Col.; *Treasurer,* Dr. Richard J. Nunn of Savannah; *Secretary,* Dr. Albert C. Geyser of New York.

American Roentgen-ray Society.—The eighth annual meeting of this organization will be held in Cincinnati, Ohio, October 2, 3, and 4, 1907, under the presidency of Dr. P. M. Hickey of Detroit. Exhibits of negatives and of apparatus will be displayed and lantern demonstrations will be used to illustrate the papers read.

The Medical Society of the County of Westchester, at its stated meeting on September 17, at the New York Academy of Medicine, listened to a paper by Dr. S. E. Getty of Yonkers on "Ectopic Gestation." The paper was based upon twenty-five cases treated in St. John's Hospital, and illustrated the advantages of prompt diagnosis and immediate celiotomy. Dr. Charles E. Nammack, president of the First District Branch of the State Medical Society, asked the participation of the members in the annual meeting of that branch, to be held in New York City at 2:30 P.M. on October 28.

New York Skin and Cancer Hospital.—An alumni association of the New York Skin and Cancer Hospital was recently organized and the following officers elected: *President* Dr. J. Francis Aitken; *Vice-President,* Dr. H. H. Whitehouse; *Secretary,* Dr. Jerome Kingsbury.

Yorkville Hospital.—At the annual meeting of the medical board of this institution, the following officers and additional members of the medical board were elected: *President,* Dr. H. B. Sheffield; *Vice-President,* Dr. O. P. Honegger; *Secretary,* Dr. M. Talmey. Dr. Abram Brothers was made visiting gynecologist, Drs. M. W. Ware and A. E. Isaacs visiting surgeons, and Dr. Ch. B. Meding visiting eye, ear, nose, and throat surgeon.

For a Chinese Hospital.—A committee of Chinese merchants of this city is planning to equip a $25,000 hospital in the lower part of the city for the treatment of Chinese patients. For the past three years these merchants have been supporting a charitable institution for the care of their sick countrymen, though the fifteen Chinese physicians connected with it had no other authorization to practise than a certificate issued by the Chinese consul affirming that the holder was a Chinese doctor of medicine. On investigation by the counsel of the County Medical Society, it was learned that through ignorance of the present laws governing medical practice in this State, the Consular office had issued the certificates in good faith. The hospital building at 105 Park street is being remodeled and will later be conducted by physicians who have passed the State Board examinations.

Columbia University.—The opening exercises of the 154th year of Columbia University were held in the gymnasium, on Morningside Heights, last Wednesday. The annual address was delivered by James Rignall Wheeler, Professor of Greek Archæology and Art, upon "The Idea of a College and of a University." The opening exercises of the College of Physicians and Surgeons were held at the college on Thursday afternoon. The address of welcome was delivered by President Butler, and Dr. George S. Huntington, Professor of Anatomy, also spoke on the methods and scope of natural object teaching in the medical course.

Post-Graduate Medical Schools in Düsseldorf.—The second medical school in Germany devoted exclusively to post-graduate instruction has been recently opened in Düsseldorf. About three years ago the first institution of this sort was created in Cologne.

Revolt of Internes.—The house staff of St. Joseph's Hospital, St. Paul, Minn., resigned in a body on August 21, dissatisfaction with their treatment by the attending staff and by the hospital authorities being alleged as the cause.

Bequest to Philadelphia Institutions.—By the will of the late Matilda Elkin of Philadelphia the sum of $5,000 is bequeathed to the Presbyterian Hospital, in memory of a sister of the decedent Margaret P. Leeds. By the will of the late Miss Amelia Priestman, bequests are made to the following charitable institutions: St. Joseph's Asylum, $2,000; St. John's Asylum, $1,000; St. Agnes's Hospital, $5,000; Pennsylvania Home for Blind Women, $2,000; Home for Incurables, $2,000; Home of the Merciful Saviour for Crippled Children, $1,000.

Obituary Notes.—Dr. George Newby died on September 19 in Flushing, at the age of eighty-seven years. He was born in England, but had lived in this country for about sixty-five years, and had practised for many years in this city. He was for some years a director of the Metropolitan Art Museum.

Dr. Elmer R. Reynolds of Washington, D. C., died on September 17 as the result of being run over by an automobile while alighting from a street car. He was born in Dansville, N. Y., sixty-one years ago and served from 1861 to 1865 in the Tenth Wisconsin Light Artillery. He was schoolmaster in the navy from 1866 to 1876, and since then had been a medical examiner in the Pension Office. He became prominent as an ethnologist and archæologist and received numerous distinctions for his work in these fields. He was the author of many monographs on the archæology of the District of Columbia, Maryland, and Virginia, and had also written several romances. He was a member of various historical and geographical societies in this country and abroad, and was one of the founders of the American Anthropological Society.

Dr. Edward Fowler of Laurel, Del., died on September 20, at the age of seventy-two years. He served on the Delaware State Board of Health for two terms, and was a founder and director of the Peninsula General Hospital at Salisbury, Md. He was a native of Spring Hill, Md.

Dr. George Archbold of Jersey City died on

September 16 of carcinoma of the liver. He was born in Ford Village, Scotland, in 1840, and received his medical degree from the University of Edinburgh. He took up chemistry as his life work and became prominent as a consultant in this science. In 1890 he was appointed chief chemist of the War Department, and during his incumbency of this office the naval laboratory at Washington was equipped. He was the recipient of many honorary degrees, and was a member of the Society of Science, Letters, and Art, in London.

Dr. CHARLES B. BRIDGHAM of Cohassett, Mass., died on September 17 of nephritis, at the age of sixty-six years. He was born in Buckfield, Me., and was graduated from Bowdoin College in 1863. He served in the Civil War as assistant surgeon, and at the close of the war began practice in Oxford County, Me. In 1887 he removed to Cohassett.

Dr. HARRIET A. LEONARD of Manitou, Col., died on September 8, at the age of seventy years. She was graduated from the Keokuk School of Medicine, and had practised in Manitou for twenty-five years.

Dr. JAMES F. DUFFIE of Blackstock, S. C., died on September 9, at the age of seventy years. He was a graduate of the Charleston Medical College, and served in the Confederate Army as surgeon.

Dr. LESTER S. HILL of Providence, R. I., died on September 9, at the age of sixty-four years. He received his medical degree from the New York Medical College in 1872, and since that time had practised in Providence. He was a member of the House of Representatives during 1872 and 1873, and was surgeon of the First Rhode Island Volunteer Infantry in the Spanish War.

Dr. J. HENRY JACKSON of Barre, Vt., died on September 13, at the age of sixty-three years. He was born in Brome, Que., and received his medical degree from the University of Vermont in 1865. He began to practise at Stockholm, N. Y., and in 1870 removed to Barre. In 1882 he was made professor of physiology in the University of Vermont, a position which he held to the time of his death. In 1903 he was elected Mayor of Barre, and he had held numerous other professional and public positions.

Dr. P. L. Murphy, Superintendent of the State Hospital for the Insane at Morganton, N. C., died on September 11, at the age of fifty-eight years. Dr. Murphy had been superintendent of the State Hospital since its establishment about twenty years ago.

Dr. V. O. TAYLOR of Athol, Mass., died on September 10, at the age of sixty years. He was born in Charlestown, Mass., and was graduated from Harvard Medical School with the class of 1868.

Dr. JOEL W. HYDE of Brooklyn died on September 22, at the age of sixty-eight years. He was born in Westbrook, Conn., was graduated from the Yale University medical school in 1857, and practised for several years in Goodrich, Conn. He served in the Civil War as surgeon, and at its close began practice in Brooklyn. Since 1881 he had been attached to the Long Island College Hospital and for years was secretary of the council. Since 1883 he had been chief of obstetrics in St. Mary's Hospital, and was also one of the consulting surgeons in the Bushwick Hospital. He was a member of many medical and other societies.

Dr. PETER M. WISE of this city died suddenly on September 22, at the age of sixty-four years. He was a graduate of the Buffalo Medical College.

Dr. WILBUR O. ATWATER, Professor of Chemistry in Wesleyan University since 1873, died at Middletown, Conn., on September 22. Dr. Atwater was born in Johnsburg, N. Y., on May 3, 1844, and was graduated from Wesleyan in 1865 and the Sheffield Scientific School at Yale in 1869. Dr. Atwater from 1875-77 was the Director of the Connecticut Agricultural Experiment Station, and was well known for his research work in metabolism and allied subjects.

Dr. WILLIAM G. B. HARLAND of Philadelphia died at Worcester, Mass., on September 13, at the age of thirty-nine years, as the result of an operation for appendicitis. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1890. He was Associate in Otology in the Philadelphia Polyclinic and Instructor in Laryngology in the University of Pennsylvania.

Dr. M. G. LESH died at Stroudsburg, Pa., on September 16 of a carbuncular affection of the face, at the age of fifty-seven years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1873. He was for twelve years surgeon for the Delaware and Lackawanna Railroad Company.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE SCIENCE CONGRESS—DEBATES ON ANESTHETICS AND ON ALCOHOL—OBITUARY.

LONDON, September 6, 1907.

IT is somewhat unfortunate that so many conferences take place at the same time. The medical and the scientific this year being held simultaneously, the discussions could hardly hold our attention at both, when the same subjects were debated. The British Association (for the Advancement of Science) has fixed next year's meeting for September 2 at Dublin and elected Mr. Francis Darwin President. The physiological section of this, the older and more important society, is always interesting and sometimes its discussions overlap those of its junior sister. This year there were two unusually able debates of special value to the profession—those on the action of anesthetics and on the use of alcohol in medical practice. The former formed the subject of the opening address of the President of the Section, Dr. Augustus D. Waller, who has devoted much time to the investigation into the condition of anesthesia and its production. From life to death by this way, he said there were three stages divided by three finger posts. Two should be carefully watched for, the third should never be sighted. During the first stage sensation and voluntary motion became suppressed, while reflex and automatic movements were preserved. The finger post between this and the next was the conjunctival reflex. During the second stage voluntary and also reflex movements were wholly suppressed (as indicated by the conjunctiva), but the automatic movements of respiration continued. This was the degree for major operations, and the finger posts to its boundaries were on this side conjunctival reflex, on that movements of respiration. The third finger post must not be passed, it was arrest of the heart's beat. Arrest of the pulse meant an almost hopeless state. Stoppage of respiration meant danger; stoppage of pulse death. This was a clear picture of the process of anesthesia and its principal danger—cardiac syncope. Dr. Waller went on to consider the dosage of chloroform and the deaths under it. He assumed that the deaths were more numerous under it than under other anesthetics because it was the most powerful and convenient and therefore more often used. This, he held, was no reason for substituting other drugs, but for more careful administration. He further assumed that chloroform was remarkably uniform and certain in its effects, acting in strict conformity with the dose and unaffected by irregularities or impurities. His experiments showed it to be the most trustworthy anesthetic. But safety consisted in continuous administration of the vapor at a strength in air of between one and two per cent. How to secure this essential limitation? Methods and apparatus were legion. All which delivered definite percentages are based on one of

two principles. On the first or vacuum system the patient inspired air through a vessel containing liquid chloroform by a broad inlet tube and a closely fitting face piece (Snow's and Harcourt's apparatus are examples). On the second or plenum system the patient inspired from a freely open face-piece in which the air and chloroform at the required percentage were supplied in excess by a pump, as in Dubois' apparatus and the wick vaporizer. By the plenum system there was a more uniform supply and the patient breathed more freely. Whatever methods were employed accurate percentage is of the first importance. It is difficult to estimate this. Dr. Waller described a simple and ready method of estimating percentages and testing the degree of accuracy to which any plan or apparatus was subject under the ordinary conditions of administration.

Sir V. Horsley moved a vote of thanks to the President and said he had made the haphazard administration of chloroform a thing of the past. He had shown that a two per cent. vapor was safe and sufficient. Dr. F. Hewitt seconded and remarked on the great value of Dr. Walker's and Professor Harcourt's work. But there were cases in which exact percentages could not be used and an underdose might be fatal. He also urged that students must be more thoroughly taught. He agreed with Dr. Waller that the plenum system was better than the vacuum. The community was deeply indebted to Dr. Waller. Professor Vernon Harcourt followed with a further tribute to the President. He deplored that death from chloroform was often put down as "misadventure." Ten per cent. had sometimes been given, and it was proved that two per cent. was enough. He had learned much from the President's address.

Prof. Schäfer thought that by watching and influencing the effect on the heart—a point not raised by the president—some fatalities might perhaps be prevented.

Prof. Schüster said the number of operations being much larger than formerly, the ratio of fatalities was less than it used to be, though still too large.

Prof. Gotch was glad that the universities, including his own (Oxford), were taking up this matter and insisting on special training of their medical students in the administration of anesthetics.

The President acknowledged the vote and remarked on the difference between a skilled anesthetist like Dr. Hewitt and the young man who often had to administer chloroform far from help, perhaps abroad or in a colony without any apparatus.

Responding to several requests, Dr. Hewitt explained his remark as to an underdose being fatal. Though when well under, he said, there was not much effect on respiration, but at the beginning of an operation various reflex effects might be set up, some implicating respiration. This if not relieved in time might go on to suspension of breathing—reflex asphyxia, due to imperfect anesthesia.

The debate on alcohol at the Science Association was on a much higher plane than the rather loose talk indulged in at the Medical Association and embraced both the physiological and therapeutic actions. The interest in this discussion was increased by the presence of a lively opposition to the total abstinence view. Dr. Waller, as president, said that the debate was not intended to deal with the question of alcohol as a beverage so much as with the effects of small doses as determined by physiological experiments and therapeutical observations.

Professor Cushing opened the discussion by remarking that, though the exaggerations of the opponents had caused a reaction in the public mind, the uses of alcohol in medicine in the past had been entirely erroneous. As to the supposed digestive qualities he endorsed Binz's dictum that a healthy stomach needed no stimulant, so no alcohol must be the standpoint of the physician to-day and that the more because of its other effects. It had been shown to behave like other nitrogen-free foods. Also it left the tissues in an impaired state and its abuse lessened resistance to invasion of pathogenic organisms. On the central nervous system the effect differed in different individuals. How often it acted as a pure depressant needed to be more generally recognized. The results of investigations on the mental state went to show that alcohol acted as a narcotic, but this would not exclude its use in therapeutics. It might be useful, but not indispensable. The president had not reached a decided conclusion as to the toxic effect. There were various forms of alcohol. He found that brandy diluted with water or with saline solution differed in effect.

Dr W. H. R. Rivers had experimented on the immediate effect of single doses, contrasting it with the habitual use, but said further experiments were required.

Dr Dixon said as to alcohol being called a poison on account of experiments on protoplasm, the same could be said of distilled water, beef tea, etc. Ethyl alcohol could be distilled from the tissues of animals or men who had never tasted it. He had been working for three years at the effect on the circulation, and thought he had proved that up to 0.2 per cent. in the blood it facilitated the work of the heart, but this was reversed when the amount was increased to 0.5 per cent. He said the man who wanted to do mental work was a fool to take it. But that was no reason why men should never take it. It was said to produce fatty degenerations—so did sugar. It had a value as food, being so easily absorbed.

Sir Victor Horsley remarked as to the previous speaker's analogy that "sugar does not make you beat your wife," and added that the well-known effect in increasing diastolic relaxation of the cardiac walls could not be regarded as a stimulation or an advantage to the circulation.

Mr. C. J. Bond presented a series of curves of the rise and fall in the consumption of alcohol at different periods from 1845 to 1900. He found them to be connected with changes in the nation's commercial prosperity, and held that as there had been a continued fall since 1900 the argument should be that the tendency was to be regretted.

Dr. Reid Hunt of Washington described his experiments on young guinea pigs, extending over two years, and designed to be strictly analogous to human beings who were moderate drinkers. The question of tolerance in animals and men had not, he thought, been duly considered. Increased power of oxidation of alcohol was acquired. Alcohol also lessened resistance to poison, but sugar increased it. He thought that most probably the continued use of alcohol produced definite physiological changes in the body processes—sometimes for good, sometimes for evil.

The President closed the debate with a brief speech, in which he said he had no conception of what was an extremely moderate dose, but he had learned from Dr. Dixon's experiments that the amounts which could be present in the blood as physiological and pathological standard amounts were 0.2 and 0.5, and they were proportional to 0.02 and 0.05 for chloroform. He hoped more definite information might be forthcoming at the next congress.

The death is announced by telegraph of Lt. Col. H. J. Dyson, F.R.C.S., I.M.S., on Tuesday last at the Presidency Hospital, Calcutta. He was only forty-seven, entered the service in 1885, was in the Burmese Expedition 1886-88, for which he held medal with clasp, and afterwards was Deputy Assistant Sanitary Commissioner in the Punjab, Sanitary Commissioner in Bengal, and Civil Surgeon at Jenore.

Dr. Walter C. Hirst of Chapeltown, Leeds, was shot dead at his own door on the 31st ult. by a lunatic, who committed suicide immediately. It seemed from a letter the assassin sent to a friend that he was under a delusion that the doctor had caused him to have fits. Dr. Hirst was M.B. Lond., 1899, and had only returned from his honeymoon a few days before the tragedy.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent)

HEALTH CONDITIONS—INEXPLICABLE CASES OF CHOLERA—A PLAGUE CASE FROM CHINA—PERSONAL.

MANILA, P. I., August 8, 1907.

THE report of the Bureau of Health for the fiscal year which ended June 30, 1907, shows most satisfactory health conditions in the Philippines. It seems probable that the effects of the sanitary reforms which have been persistently carried out during the past few years are commencing to show in a most concrete manner. The public health is probably more satisfactory than at any time since American occupation of the Philippines, from which it is reasonable to infer that health conditions are better now than at any time for the past one hundred years or more. The death rate per thousand for the city of Manila has been reduced from 40.09 to 30.01, and if the deaths from cholera, which prevailed largely last July (1906), could be deducted, the rate would be about 28 per cent., which compares favorably with many cities of the United States. The present rate from all causes already ranks Manila as one of the tropical cities with the lowest death rate. The rate for Americans during the year was only 5.59, which is a reduction of 3.75 over the previous year, and among Spaniards and other Europeans it dropped from 17.40 to 15.84.

There has not been a single case of plague in the islands for more than a year, and probably less smallpox than at any time since the American occupation. In those provinces where the number of deaths annually from smallpox alone was six thousand, not a single death took place from this cause.

The solution of the leprosy problem has passed from the theoretical to the practical stage; the number of

lepers September 1, 1905, being 3,580, and for the year which is just ended, 2,826.

So far as is known, no cases of cholera have made their appearance in Manila since November, 1906, until July 13, 1907, when a man was removed from a lighter in the river, who had a history of having eaten a large quantity of sour rice. His clinical symptoms were rather those of a severe ptomain poisoning than those of cholera. He died a few hours after arrival at the hospital, and, on post-portem examination the gross pathological findings were not typical of cholera, but a bacteriological examination of the intestinal contents revealed the cholera organism present. Whether he actually died of cholera or from acute ptomain poisoning it has not been possible to determine accurately.

On July 15 another case, with all the clinical symptoms of cholera, was found in the person of a launch engineer who had arrived in the city of Manila three days previously from the province of Sorsogon. He was removed to the cholera hospital, and the laboratory examination showed that the spirillum of Koch was undoubtedly present. He died three days later, with all the clinical symptoms of cholera. On autopsy the gross pathological findings were typical. The man came from a province in which no cholera is known to have been present for more than three years, but in view of the fact that the experience of the last few years has shown that in the great majority of instances the incubation period for cholera is less than forty-eight hours, it is reasonable to infer that he must have contracted the disease in the city of Manila. No further cases occurred until July 23, when an old lady who resided on Calle Magallanes, in the Walled City, was suddenly seized with the symptoms of cholera. She was removed to the cholera hospital and found to have all the typical clinical symptoms of the disease, and, in addition, to be positive upon bacteriological examination. This woman resided in a family with eight other persons; ate at the same table as other members of the family, and with a history that she had not left the house for some days previous to her illness. The family was kept under close observation for more than five days, but no symptoms suggesting cholera could be detected, nor have any other cases been found among residents of the Walled City. The next case occurred August 5, in the person of a Japanese fisherman who resided in the district of Tondo. So far as the history of his illness is concerned, it was similar to the case reported above. The appearance of this disease among these different people, who have no connection with one another, and live in widely separated sections of the city, is almost inexplicable, from the behavior of cholera as generally taught in text-books, or from any experience heretofore had in the Philippines. It is most difficult to understand how the infection could have taken place in these cases, and it is still more strange why the disease does not show more tendency to spread.

On July 23, 1907, there arrived in the port of Manila the steamship *Ferd Lacisz*, from Chinese ports, the last port of call being Hongkong. At the quarantine inspection of the vessel a case of plague was found in the person of a Chinese member of the crew. He was removed to the plague hospital and the vessel sent to Mariveles for disinfection and fumigation. At the end of seven days the vessel was released, no further cases having made their appearance.

Colonel L. M. Maus, United States Army, who was formerly Commissioner of Public Health for the Philippine Islands, arrived here August 4, 1907, for another tour of duty in the islands. He has been assigned as Chief Surgeon of the Department of Luzon, with headquarters at Manila. He takes the place of Col. John Van Hoff, who was made Chief Surgeon of the Philippines Division upon the return to the United States of Colonel Byrne.

Captain George H. Gosman, Medical Department, United States Army, who has been stationed at Camp Downes, Leyte, during the past two years, has been ordered to return to the United States on the August transport.

Corneal Abrasions.—In order to render abrasions or ulcerations of the cornea clearly visible ophthalmologists instil a very minute drop of a 2 per cent. solution of fluorescin. The excess is washed out and any areas denuded of epithelium become conspicuous through their taking up the green stain.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 12, 1907.

Operative Treatment of Varicose Veins of the Lower Extremity.—After some remarks an anatomy, J. L. Bottomley passes in review the Trendelenburg, Schede, and Madelung operations. He sums up by saying that: (1) The important etiological factor is a congenital one; in a small proportion of cases it is inflammatory. (2) The operation that will give the best results must have as its essential feature extirpation of the internal saphenous vein; but to this such other procedures must be added as are suitable to each individual case. (3) Before operative measures are undertaken it must be demonstrated that the deep venous circulation of the lower extremity is not obstructed to any marked degree. (4) In properly selected cases, it is believed that a permanent cure may be promised. (5) The operation is almost, but not entirely, free from danger. Bottomley has had fifty-seven operative cases in the last three and a half years, in conjunction with a hospital colleague, and, while he has tried the various methods above indicated, he prefers the one about to be described. He extirpates the internal saphenous vein as low as possible; all incisions are closed by lock sutures of horsehair and covered with collodion dressings. Eczematous areas are covered with compound tinctures of benzoin; superficial abrasions are wiped with iodine tinctures before operation. Duration of stay in bed averages two weeks. A bandage from toes to knees is usually recommended for the next three or four months. The operation preferred by him is that suggested by Mayo, although it is not applicable to any individual case. The leg is held elevated and extended. The internal saphenous is then divided between hemostats in the upper third of the thigh. The proximal end is ligated and the distal end is threaded into the ring of an enucleator and again grasped by a hemostat. The vein put under moderate tension is then extirpated subcutaneously by pushing the enucleator in the direction of the knee. When six to eight inches of the vein have thus been freed, the ring is pushed up against the skin from underneath, a short incision made down on it, the vein grasped, enucleator withdrawn, the freed segment pulled out, rethreaded into the ring, and the process repeated down to a point from four to six inches below the knee. If the main trunk breaks during the operation, pressure is applied over the point of rupture, and incision made lower down, the vessel divided between hemostats and extirpated from below upwards to the point of rupture. Incisions in and very close to the fold of the knee are avoided owing to the danger of keloid in that locality. Various operative details are elaborated in the original paper.

Rectal Anesthesia.—J. H. Cunningham reviews the historical and clinical aspects of this method of inducing narcosis. He believes that it may be employed to produce narcosis preliminary to the administration of ether by the mouth, especially if the patient is known to take ether badly. He has devised a special apparatus to overcome rectal disturbances and to control the degree of anesthesia. In his own cases there had been no diarrhea or bloody stools. In a few cases temporary colicky pains and painful abdominal distention have been present. Details of administration cannot be discussed here. The author believes that the lung eliminates ether as fast as the rectum absorbs it, so that danger is lessened. Comparatively little ether is required. There is no stage of excitement. Vomiting is infrequent. Excess of secretion is reduced to a minimum. Recovery is rapid. The paper is an excellent exposition of the general question of rectal anesthesia.

New York Medical Journal, September 14, 1907.

Electrolysis and the Nervous System.—Sir J. A. Grant gives the clinical histories of four cases. He says that the umbilicus may be considered the storm center so far as collateral influence on the sympathetic is concerned. Here not only is the solar plexus near the surface, but there are wide and extensive anastomoses with all the visceral nerves, and it has extensive connections with the cerebrospinal axis. Consequently electrolytic treatment applied at this site will have a maximum effect for good. When the tear and wear become changed by electrolytic action, so as to afford the freer transmission of nerve force, the constitutional changes for the better become more marked. Of especial value is this treatment in disturbances of the alimentary canal where the weak defences of the system allow the entrance of bacterial toxins. Very fre-

quently imperfect digestion is followed by gradual debility, and moderate edema of the extremities entirely outside of renal, cardiac, or hepatic complications. Under such circumstances the local application of electricity to the abdominal walls brings about a change for the better. Energy is restored to the ganglionic centers, the dilated and clogged colon gradually resumes its normal caliber and functions, while owing to the increased activity of the absorbents the dropsy is removed. The author has frequently observed in regions of the limbs a lessened degree of sensation to the electric current of short duration. He considers this defective response as interesting in the light of the clefts or indentations in the medulla of the axis cylinder, defined by various physiologists as small irregular masses separated by fluid. This may account for an imperfect nervous impulse, the importance of which cannot be overestimated, provided the sudden return of complete sensation is the result of electrolytic action restoring the continuity of the medulla of the axis cylinder.

The Ideal Ligature.—The results of extensive investigations by A. D. Whiting lead him to present the following conclusions: (1) The ideal ligature is obtained by treating catgut before it has been twisted into a solid cord or string. (2) Catgut treated before it is twisted is much stronger than catgut sterilized after it has been made into a solid cord or string. (3) It is possible to thoroughly impregnate the untwisted gut with a chemical which will become a component part of the catgut when twisted. (4) Silver iodide gut will remain sterile as long as it is retained in the living tissues and will possess germicidal powers until it has been absorbed or replaced by living cells, the fluids of the body breaking up the silver iodide into silver, iodine, and various compounds of these chemicals. (5) It is possible and practicable to produce catgut that is absolutely free from germ life and that has antiseptic and germicidal powers by treating the gut with various chemicals before it is twisted into a solid string or cord.

Movable Kidney in the Genesis of Bile Duct Disease.—Basing his opinion on the observation of ten cases reported in his paper, A. E. Gallant proposes as worthy of at least tentative adoption the following conclusions: (1) That the inception of disorders of the biliary tracts arise from traction or pressure on the bile ducts by a prolapsed kidney. At first there is but slight mobility, slight traction, and a slight attack, of a "bilious" nature, with or without jaundice. It is owing to the transitory nature of the attacks during its incipiency that examination is but seldom made, or the kidney cannot be palpated because it has slipped back, as soon as the patient lies on her back, and the gall-bladder empties itself as soon as the tension is released. The mobile kidney gradually increases in size and mobility, exerting greater traction, causing greater obstruction, greater bile stasis, greater colic and jaundice, with infection, precipitation, stone formation, ulceration, perforation, and sometimes cremation. (2) That these attacks can almost always be arrested and the diagnosis established by placing the patient in a bed with the foot raised ten inches, and replacing the kidney by careful manipulation. (3) That by the early recognition of the kidney mobility as the cause, in the early stage of the disease and the early wearing of a special corset, exacerbations can be prevented, further progress of duct disease avoided, gallstone formation eliminated, operations for its removal reduced to a minimum, and at the same time by the use of the corset we overcome the bad effects arising from ptosis of other abdominal viscera. (4) When pain, fever, and jaundice do not diminish or subside within twenty-four to forty-eight hours, or unmistakable signs of severe infection or peritoneal invasion are present, operate quickly and thoroughly.

Traumatic Edema in the Cornea of the New-born Infant.—An interesting case in which it was necessary to distinguish between congenital corneal opacity from intrauterine keratitis, corneal abnormality from faulty embryonic development, superficial keratitis and hydrophthalmus, is reported by A. Bray, whose patient seen thirty-six hours after instrumental delivery exhibited a white covering over the cornea of the left eye. The entire eyeball bulged somewhat, and there was a conjunctival hemorrhage. These two latter conditions were undoubtedly due to the forceps, but the author felt less certain as to the nature of the corneal difficulty. The natural treatment in such a case is expectant, as time will restore an edematous cornea to a normal condition. In the case reported to the author used a one per cent solution of dionin, which he believed hastened the absorption of the exudate by increasing the activity of the lymphatic elements in the cornea. He was not sure as to the outcome until the effects of the manifest trauma to the organ as a whole could pass off, but in six days the cornea was clear, the eyeball had assumed a normal shape, the fundus reflex was well seen, the cornea was of good luster, and the opacity had entirely disappeared.

Journal of the American Medical Association, September 21, 1907.

Prevention of Peritoneal Adhesions.—E. Marvel recommends the use of adrenalin chloride after separating peritoneal surfaces to prevent readhesions. He allows the solution to flow from an irrigating nozzle over the oozing surface. The natural method of preventing adhesions is removing the exudation by absorption and the peritoneum can take care of it; but subsequent exudation should also be prevented. By its vascoconstrictor action, adrenalin shuts off further leakage, and the normal salt solution in which it is dissolved also serves to keep apart the separated surfaces. He uses a dram of the adrenalin chloride solution to one quart of normal salt solution, making approximately a strength of 1 to 50,000; the temperature ranges 100° to 110° F., and the amount used varies from 500 to 1,500 c.c., according to the size of the cavity and the extent of the adhesions.

Intestinal Obstruction.—R. D. McClure gives a detailed account of experiments undertaken to answer the question as to the cause of the symptoms (vomiting, collapse, disturbances of blood pressure, sweating, etc.) following intestinal occlusion, whether they are reflexes from nervous irritation or are due to the absorption of poisons from the obstructed intestine. His methods were along lines similar to those of previous experimenters (Kukula, Albeck, and others), and consisted in introducing some of the contents of an obstructed intestinal loop of a dog that presented the above symptoms into the isolated loop or the peritoneal cavity of another dog. When this was done into the peritoneal cavity the symptoms appeared, but the animal soon recovered; but when the intestinal content was introduced into a loop entirely isolated, the continuity of the gut having been re-established by anastomosis, death always occurred in a few days, with symptoms like those of obstruction. In all instances the isolated loop became greatly distended and contained great numbers of bacteria, as in ordinary obstruction. It evidently acts like a culture tube, and it would seem that the symptoms and death were due to the absorption of toxins from the bacteria. Still, not all the experiments were free from objections, as in several the mesentery became twisted, interfering with the vitality of the loop, and in one or two ulceration and perforation occurred. Excluding, however, conditions of ulceration leading to peritonitis, or those in which infarction renders the walls permeable to bacteria, it seems that obstruction may persist for days with enormous distention of the gut and growth of bacteria. The bacterial poisons alone may be absorbed, while the germs themselves do not leave the intestinal lumen. It seems probable that this may also occur in man, though there may be a later invasion of the tissues by bacteria with septicemia. In animals the symptoms are such that it is difficult to see how irritation of the intestinal nerves can be their cause, and it seems just as reasonable to assume that in many the symptoms of obstruction are rather the result of intoxication than of any mechanical disturbance of the nervous mechanism of the intestinal wall. The article is illustrated.

Postoperative Ileus.—F. Martin reviews the literature of postoperative mechanical ileus, showing from this and other evidence that it is not a rare complication and that it occurs after laparotomies of all kinds, in percentages ranging anywhere between 0.1 per cent. and 2 per cent. Its diagnosis, while of the utmost importance, is sometimes exceptionally difficult. There is an early syndrome of obstruction—a sort of pseudo-postoperative ileus, which clears away, but which may mask the symptoms of the more formidable condition. Then, if the case is of the strangulation type, every hour of delay jeopardizes the patient's chances. One of the most important symptoms, in Martin's opinion, is the intense and, though with slight remissions, persistent abdominal pain, usually referred to the umbilicus; there is generally slight change in temperature or pulse; there is soon persistent vomiting, and marked peritoneal shock following; very high leucocyte count, anywhere from 30,000 to 40,000. Soon assymmetrical distention is noted, and later on Von Wahl's loop and visible peristalsis. In mechanical obstruction the pulse is not much disturbed; it is full and of good tension. In peritonitis on the other hand, the pulse is small and the tension low. The symptoms are described in consider-

able detail. The prognosis of post-operative mechanical ileus is better than that of the paralytic or adynamic type, but depends largely on how soon operative procedures are resorted to, and also on the nature of the original affection calling for laparotomy. In the absence of infection, the prognosis is usually good. As the chief causal factor is adhesions, operation is the only rational treatment. A number of cases are reported.

An Improved Inhaler for Anesthesia.—W. C. Pedersen describes an inhaler devised by himself to meet the requirements of: 1. Leaving the normal work of the lungs unaffected. 2. Offering no obstruction to the inflow and outflow of the tidal air. 3. Allowing the admission of fresh air with each inspiration, and controllable by the anesthetist. 4. Preserving sufficient expired air and ether fumes to warm the fresh ether fumes, thus reducing refrigeration. The first two requirements are met by taking two tubes larger than the adult trachea, fitted gastight over each other, with two matching windows opposite each other, so that when the indicator is at the word "air" of the scale the windows are closed, and when it is at the word "ether" they are wide open. Outside the windows of the outer tube, screened with wire gauze, is the packing of the ether chamber. Breathing through a tube larger than his own trachea, the patient evaporates his ether from the ether-soaked gauze in the windows in a manner provided for in no other inhaler known to Pedersen, and has, besides, no obstruction of his tidal air to overcome. Fresh air is admitted with each inspiration by means of the inspiratory valve at one end of the T-formed bag-carrier. This fresh air is controlled by the cut-off valve just within the tube. Warming of the ether fumes is afforded as in other bag inhalers—by the bag which receives and stores the warm expired ether fumes, to be rebreathed by the patient mixed with fresh ether fumes from the windows. All the details of the inhaler and its mode of use are given, with illustrations. It can be used, according to the author, with the following anesthetics and sequences of anesthetics: 1. For gas alone. 2. For gas and air in definite proportions. 3. For gas and oxygen in definite proportions. 4. For gas-ether sequence. 5. For the gas-ether sequence with oxygen. 6. For the ethyl-chloride-ether sequence. 7. For the ethyl-chloride-ether-oxygen sequence.

Salpingitis Caused by Appendicitis.—I. S. Stone reports two cases of salpingitis due to disease of the appendix, and emphasizes the fact that such cases occur and are more frequent than is generally supposed. He was able not only to observe the appearance of the diseased organs, both before and after removal, but also to note clinical and pathological differences existing between these cases and those of the more common gonorrheal origin. The gonorrheal diplococcus tends to close the fimbriæ and to protect the peritoneum until the tubal mucosa has been destroyed, and perhaps rupture occurred. Streptococcic and staphylococcic infection, on the other hand, cause lymphatic and connective tissue invasion. In both his cases the colon bacillus was present, indicating intestinal origin of the disease. Unfortunate mistakes in diagnosing the gonorrheal salpingitis have occurred because of the non-recognition of the possibility of this other route of infection.

The Lancet, September 7, 1907.

The Treatment of Cancer.—L. Drage regards the surgical treatment of cancer as absolute. Several years ago he called attention to the possibility of relieving cancer patients by the artificial production of leucocytosis, which denotes an increase in the cells of the blood which are most highly endowed with the properties of living cells. The first drug used for this purpose was cinnamate of soda. He reports several cases with favorable results under this general plan of treatment. The author admits that the published reports of his work have made practically no impression on the surgeons. By cooperation with the Buffalo (N. Y.) Laboratory for Cancer Research, he has been able to avail himself of certain new substances, viz., coumarate of sodium and tylmarin. Life has not always been saved, but has often been prolonged, while suffering has been greatly relieved. He believes that much is to be expected in the future from the employment of these new substances and of others which may be elaborated. The author further claims that very definite results have been obtained in connection with the prevention of local death of the tissues invaded and the absorption of the products of decomposition into the system. In his experience in the old days a large proportion of the cases died septic, but no case treated by him with the new remedies has so died. The drugs used are very active in destroying all forms of fission fungi. Tests by the Rideal-Walker method against the typhoid bacillus showed the activity of tylmarin as 4.5, carbolic acid being taken as 1, while that of ortho-coumaric acid was 6.5. That of formalin under the same conditions was only 0.30.

Pyemia Due to the Influenza Bacillus with Multiple Arthritis and Meningitis.—L. S. Dudgeon and J. E. Adams report a case, their patient being a girl baby of ten months. Full clinical and post-mortem notes are given. The bacteriological tests showed the influenza bacillus in the various joints affected. The primary lesion seems to have been epiphysitis of the upper extremity of the radius. There was no evidence of any sore or wound on the limbs, as sometimes met with in cases of acute epiphysitis and osteomyelitis due to the *Staphylococcus aureus*. There was no history obtainable of any influenzal affection in any other member of the family, and apart from the fact that the child was not thriving for one month before the onset of this disease her condition caused no anxiety. When first seen the case appeared obscure and examination by *x*-rays failed to throw further light on the exact lesion. This was doubtless due to the absence of ossification in the epiphysis and the very small amount of destruction of bone at the time this examination was made. At the post-mortem examination, however, there was irregular pitting at the upper end of the radial shaft which would have been rendered evident had a second skiagram been taken. The disease proceeded with great rapidity both in the elbow joint and also as regards the systemic infection, and the sequence following the radial epiphysitis appears to have been first the elbow joint and then the right hip joint, followed very closely by the diffuse meningeal infection, and terminating in acute bronchopneumonia. From all these situations, except the lungs, the influenza bacillus was obtained in pure culture. The splenic juice gave a similar result, while microscopic sections of the lung showed a bacillus morphologically identical present in the polymorphonuclear neutrophiles. The pus in the hip joint showed no such definite characteristics.

Peritonitis and Its Treatment.—J. Berry thinks that the surgery of the peritoneum has been overdone. The doctrine, "here is a septic focus; let us take it out at all costs," as applied to appendicitis, is, in his judgment, productive of much harm. He pleads not for the abandonment of operative measures, but for more discrimination in the choice of an operation. He believes that if we should all go back to the old treatment of appendicitis in vogue twenty-five years ago, the mortality from the disease would be less than at present. We do not get the full records of the unsuccessful operations. If we did we should be appalled at the showing, taking all results, good and bad, together. By far the most serious and dangerous forms of peritonitis produced by appendicitis are those in which it is not the appendix which suddenly ruptures, but an abscess that has slowly and quietly formed outside the appendix and ruptures secondarily through its wall. When the peritoneum is suddenly invaded by bacteria there is an immediate rush of blood to the affected area. The abdominal veins are capable of holding a very large quantity of blood, and a very large quantity of blood is now needed for the great fight which is to take place between the blood plasma and white corpuscles on the one hand and the bacteria on the other. The abdominal viscera then, and especially the great omentum, become engorged with blood. This filling up of the abdominal veins leaves less blood in other parts of the body. Hence in severe cases we have collapse. The arteries are empty and the pulse is feeble. The author admits that other factors, such as reflex inhibition of the heart, may play a part in the production of shock, but he lays special stress on this cause of the shock and feeble, rapid pulse that we may meet with in peritonitis because it ought to teach us that the proper mode of treatment is to replenish the empty vessels by giving the patient fluid, plenty of fluid, to replace that which has gone off to the abdomen. For general purposes of treatment Berry makes four classes of cases: First, no perforation of a viscus and no peritoneal fluid. Here free saline purgation with large amounts of fluid by rectum or hypodermoclysis will often suffice. Opium should be avoided. Second, recent perforation of a hollow viscus. Immediate operation Third, considerable peritonitis involving much of the cavity with more or less tendency to concentration of the inflammation in one place. Immediate operation is not always necessary. Purgatives and large enemata should not be given, nor food by the mouth. Small

arterial enemata will often carry the patient over, and he can do well enough for a day or two without food at all. Fourth, general diffuse peritonitis with general distention and purulent fluid diffused over a large area. For this form the author believes that the Ochsner method of treatment will give, on the whole, the best results.

Berliner klinische Wochenschrift, August 26 and September 2, 1907.

The Differentiation of Sporadic Cases of Epidemic Cerebrospinal Meningitis from Other Forms of Meningeal Disease.—Hölker is of the opinion that although the direct transfer of infection from a patient with meningitis to persons in his environment has only rarely been proved, cases of the disease should, however, be kept in isolation. In sporadic cases of epidemic meningitis the diagnosis is often difficult to make early in the disease, particularly as the specific organism sometimes does not appear until very late. Of fifteen cases sent to the Charité Hospital of Berlin with the diagnosis of epidemic cerebrospinal meningitis a definite diagnosis could be made during the first week from the bacteriological findings only six times, two of the cases being instances of epidemic meningitis. In two other cases the diagnosis of epidemic meningitis was confirmed later on, while in seven cases the examination of the spinal fluid did not afford ground for diagnostic conclusions. In the four cases of true epidemic meningitis the meningococcus was sooner or later identified, though in one instance not until the fifth week, and it is this fact that leads the author to emphasize the necessity for caution in the disposition of suspected cases.

The Effect of Radium Emanations on Man.—Loewenthal has found that the use of water impregnated with radioactive substances is beneficial in cases of certain affections both when added to the water used for bathing cures and when given internally. A favorable effect is to be observed in cases of chronic articular rheumatism of moderate severity, regardless of whether the condition started as a chronic affection from the beginning or was the result of an acute or subacute invasion. Typical cases of arthritis deformans are not susceptible of improvement in this way, and the author believes that this fact may be of use in differentiating this obscure symptom complex from the true rheumatic affections. Another group of affections capable of being influenced by the emanations consists of the forms of chronic neuritis. Improvement was observed in cases of sciatica and of brachial and facial neuritis. Two specimen cases are described in detail in which chronic articular rheumatism and sciatica were entirely relieved by means of brine baths plus radioactive emanations, and a relapse in each case was cut short by the internal administration of radioactive water as the sole therapeutic measure.

Gonorrheal Pyelitis.—Sellei and Unterberg state that it is a matter of the greatest difficulty to determine whether or not a pyelitis can be produced by the gonococcus alone. The requisite information can be obtained only by ureteral catheterization, but there is always a possible source of error through the contamination that is likely to occur during the passage of the instrument through the urethra and bladder. By taking especial precautions in observations on five patients the authors reached the conclusion that the gonococcus alone is sufficient to produce pyelitis, although in most cases mixed infections are present. The process appears to be the result of direct ascension and not of hematogenous transmission. The affection is usually unilateral and the symptomatology is not characteristic, so that the diagnosis can be made with certainty only with the ureteral catheter. The temperature is considerably elevated only during the most acute stages; later on there are only slight intermittent elevations. In some cases fever and pain are entirely absent. The polyuria and pyuria appear to be constant, however, but these symptoms are also common to other forms of pyelitis. In most cases the process may be cured by rest and internal medication. Where these measures are ineffectual lavage of the renal pelvis is indicated. For this purpose boracic acid solution and 1 per cent. silver nitrate solution may be used.

Muenchener medizinische Wochenschrift, August 27, 1907.

The Gastric Disorders Accompanying Chronic Lead Poisoning.—Wałko has studied the gastric manifestations present in forty-three cases of lead poisoning of various degrees of intensity and chronicity. In most cases the symptoms of intoxication had persisted only for a few weeks and were very severe. As a result of his observations he concludes that even in the early stages of chronic plumbism functional disturbances of the stomach appear which may be characterized by a diminution or entire absence of hydrochloric acid and ferment secretion. At first there may be increased motor activity, which is later followed by a diminution in motility. The course of these gastric affections is very protracted, and the disturbances are partly purely functional in nature and more rarely are due to actual parenchymatous changes in the mucous membrane. They may be induced through the constipation accompanying the chronic intoxication or through the involvement of the gastrointestinal nerve plexuses. The prognosis is usually favorable even in cases of marked severity, though there is always the possibility that later on other evidences of intoxication, such as encephalitis, may appear.

The Experimental Reversion of Mouse Carcinoma to the Type of Adenoma.—Apolant says that the conditions existing in the growth of a malignant tumor may be compared to the course of a stream which remains in its normal bed as long as the banks offer the necessary barrier to the flood. If these natural barriers are broken, however, either through a rise in the waters, corresponding to the increased avidity of the tumor cells, or through destruction of the banks, which would correspond to the weakening of the powers of resistance of the organism, the inundation can be impeded only by the erection of artificial obstacles or dams. That some such measures are actually possible of application is shown by experiments on mice in which the author succeeded in causing malignant carcinomatous growths to revert to the benign adenomatous type in consequence of a procedure of immunization. In one set of cases this was effected by injections of juice from virulent spontaneous tumors and in the other by the injection of blood from healty mice. In a considerable portion of cases the reversion of the previously malignant tumor was observed. The author regards these experiments as further evidence in favor of not attempting to differentiate too sharply the adenomatous growths from the cancers, since the fact that a transition may occur from the benign to the malignant forms and back again indicates the advisability of regarding the entire group of new growths as more or less of an entity.

Composition of Human Milk and Its Chemical Analysis.—H. Lescoeur believes that the ordinary methods of chemical analysis of human milk are misleading and useless. In the cow the amount of cream obtained depends on the period of the milking at which the specimen is taken, the most cream coming at the last. In the woman the sample taken is very small and does not represent the total product. Therefore the variations in the total solids depend mainly on the variation in the amount of cream. A much more useful test depends on the density of the whey. When mother's milk coagulates there is no separation of curd, as in cow's milk, but proper filtration will separate the milk into a precipitate and an opaline liquid. The density of this liquid normally will be 1036; when the milk is poor it will vary down to 1033. A milk, then, whose density is below 1036 is a poor milk. Variations in the solids of the milk result from the age of the milk, return of the menses, pregnancy, and disease, and they are a matter of quantity, not of quality, since there is little difference among nurses in quality. In case of defective nutrition, substances are separated from the milk that are injurious to the infant, but these cannot as yet be discovered by chemical analysis.—*Le Nord Médical*, July, 1907.

Human Actinomycosis.—L. Thevenot says that in France actinomycosis is not as rare as is ordinarily stated. The cervicofacial form is most frequent, and that of the limbs is rare. That of the pleura and lungs is relatively common. The diagnosis is difficult and many cases are regarded as tubercular. The sputum is examined for the tubercle bacillus and the characteristic yellow granules of actinomycosis are passed by. Only when abscess is formed is the disease recognized. The author has studied eight cases of the disease; in only one of them were there any general symptoms; they were lack of appetite, emaciation, and mild fever. In all the cases iodide of patassium in doses of two to five grams brought about a complete cure. In none of them was there a recurrence. It is necessary to look for this disease in order to find it. That being done, we shall see it more and more frequently. The recognition of a new growth, the finding of yellow granules, and the microscopic examination are the diagnostic points.—*Lyons Médical*, May 19, 1907.

Book Reviews.

Experiments on Animals. By Stephen Paget, with an introduction by Lord Lister. Third and Revised Edition. New York: William Wood & Company, 1907.

The camps of the antivivisectionists are so largely occupied by those beyond the appeal of reason that it is doubtful whether even so admirable a work as the present is destined to make many converts among the well meaning but ill-advised defenders of this curious creed. That some unnecessary suffering has been caused in the effort to advance medical science by laboratory methods no one can deny, but the advantages to humanity that have been conferred as the result of animal experimentation are so incalculable that it is difficult to understand the attitude of mind of those who would close this avenue to further progress. Mr. Paget's volume is really an epitome of the history of medicine as we know it, and is so clearly written that it should be intelligible to the educated layman. It may be commended warmly both to medical readers (on account of its general interest) and for circulation among the public, at least that part of it that requires demonstration of what to most people is a self-evident proposition. The first section deals with the benefits resulting from the experimental study of physiology, the second with those related to experiments in pathology, materia medica, and therapeutics, and the third to a discussion of the British legislation referring to experiments on animals. The closing section is an exposition of the case against antivivisection and forms a most convincing arraignment of its adherents.

Klinik für Psychische und Nervöse Krankheiten. Herausgegeben von Robert Sommer, Dr. med. et phil., o. Professor an der Univ. Giessen. II. Band. 1. Heft. Inhalt: I. Rauschburg, Dr. Paul, Leiter des psychologischen Laboratoriums an den ung. Kön. heilpädagogischen Instituten zu Budapest: Ueber Art und Wert Klinischer Gedächtnismessungen bei nervösen und psychischen Erkrankungen. II. Lechner, Hofrat Prof. Dr. Karl, in Kolozsvár (Klausenburg): Die Schlaflosigkeit infolge von Störungen des Vorschlafes. III. Hampe, Dr. J., Nervenarzt in Braunschweig: Beitrag zur Psychologie der Aussage. Halle a. S.: Verlag von Carl Marhold, 1907.

Very interesting and suggestive to the psychiater, especially Part I, by Dr. Rauschburg.

A Treatise on the Principles and Practice of Medicine. By Arthur R. Edwards, A.M., M.D., Professor of the Principles and Practice of Medicine and Clinical Medicine in the Northwestern University Medical School, Chicago; Attending Physician to Wesley and Mercy Hospitals. Philadelphia and New York: Lea Brothers & Co., 1907.

This is a new treatise on the practice of medicine by a new writer, and one is tempted to ask whether it is needed. There are several modern books on the subject already in the field and every newcomer must therefore justify its birth by demonstrating its superiority in one or more points over its rivals. In one important point—the most important point indeed—this book is superior to one at least of its predecessors; that point is treatment. Under the malign influence of a former authority in American medicine, therapeutic nihilism at one time threatened to dominate medical practice in this country. Fortunately a reaction has set in and the authority who once held sway is now placed as a pathologist rather than a therapeutist. In this book the cure or alleviation of disease is proclaimed as the final object of medical study. The author, while not apparently an optimist, is at least not a pessimist, and there is in his work a note of hopefulness in the treatment of disease which comes as a cooling zephyr to dispel the sultry mists that have beclouded medical practice in this country. We welcome it as a sign of the times and as an indication that the practitioner of the future will not fetter himself with the formula, "a self-limited disease," and its corollary, "expectant treatment." The author is not as hopeful as the modern practitioner is justified in being, and he omits mention of many remedies which have proved their efficacy in the hands of other competent men; nevertheless, he counsels action in the presence of disease and for this we are thankful.

The arrangement of the work is such as to facilitate ready reference, different styles of type being used to indicate the various sections and their varying degrees of importance. The author is not as careful as he might have been in certain directions. The name of the yellow fever mosquito, for example, is not *Culex fasciata*, nor is the name of the Havana physician who first made this great discovery spelled Findlay. Ballottement is not a good name for the fluctuation obtained in ascites. There is no such word as sanitoria, yet this is used repeatedly. Other incorrect words, such as hydrogogue and Neuheim, may be put down to faulty proof-reading, of which there are many instances in the book. It is trying to find, in a book published in the present year of grace, that cyestrain as a factor in the etiology of migraine is dismissed with a quotation from Möbius that "this cause is epidemic in the United States." In the section on the treatment of pneumonia, even if the author had not thought it worth while to speak of the quasi-specific effect of calomel in large dose, of quinine, and of carbonate of creosote, something at least might have been said of the benefits of open air, or at least of proper ventilation of the sickroom. These and other important defects are present, but we are disposed to forgive them in observing the general tone of therapeutic hopefulness which pervades the work. In this respect Edwards' Practice is to be warmly commended to students and young practitioners.

Ulceration of the Cornea. By Angus Macnab, B.A., B.Sc., M.B., Ch.B., F.R.C.S., Chief Clinical Assistant Royal London Ophthalmic Hospital. New York: William Wood & Company, 1907.

This work, which forms a small volume of 196 pages, is written in a vigorous, authoritative style and displays a very comprehensive acquaintance with the subject. The writer has undertaken to classify ulcer of the cornea according to the determining cause, namely, the bacteria to the presence of which the ulcer is due. Those forms in which a specific microorganism is not known are considered separately. The study of ulcer of the cornea from this point of view not only imparts a knowledge of the various clinical pictures that individual species of bacteria may produce, but it makes it possible to formulate exact and effective methods of treatment.

The work begins with a short chapter on "Methods of Examination." The various forms of ulcer of the cornea are then described quite fully, and the work is concluded by a short chapter in which the "Operation for Excision of the Lacrymal Sac," the "Saemisch Section," and the "Corneal Plastic Operation" are described. A number of excellent illustrations are found in the text.

The author is to be congratulated on the production of a work which frees the subject of which it treats of much ambiguity. Every ophthalmic surgeon should familiiarize himself with the contents of this brochure.

Studies from the Zoological Laboratory of the University of Nebraska. No. 70. Iconographia Parasitorum Hominis. By Henry B. Ward. A collation of figures with brief explanatory text, to aid in the study and diagnosis of the less common parasites of man. For ready reference of students in pathology, clinical microscopy, medical zoology and comparative medicine. Lincoln, Neb.: published under the direction of Henry B. Ward, 1907.

This pamphlet contains twenty plates, each with several figures, and facing each plate are short explanatory notes. This explanatory text is exceedingly brief, and might with advantage be enlarged. The student will find this little work of real value for reference, and it will also serve as a supplement to the well-known Leuckart charts.

A Primer of Psychology and Mental Disease. For Use in Training Schools for Attendants and Nurses, and in Medical Classes, and as a Ready Reference for the Practitioner. By C. B. Burr, M.D., Medical Director of Oak Grove Hospital (Flint, Mich.) for Mental and Nervous Diseases, etc. Third Edition, Thoroughly Revised. Philadelphia: F. A. Davis Company, 1906.

In this third edition the author has rewritten the section on insanity to conform with the Kraepelin classification, and has added treatment. The section on psychology has been revised. The book is, perhaps, better suited to the medical student, or general practitioner, than to the mental capacity of the average attendant.

Surgery of the Rectum. By Fred C. Wallis, B.A., M.D., Cantab., F.R.C.S., Surgeon to Charing Cross Hospital, St. Mark's Hospital, and the Grosvenor Hospital for Women and Children, London. New York: William Wood & Company, 1907.

The first five chapters contain the author's original views of the cause and treatment of most of the inflammatory affections in and around the rectum. The operation for excision of hemorrhoids is fully described. The author strongly inclines to the opinion that rectal ulceration is not a syphilitic affection. The various operations for rectal carcinoma are fully discussed. The book presents the surgery of the rectum in a practical and condensed form. Original drawings are freely inserted.
